MANUAL
OF THE
DISEASES OF THE EYE

FOR STUDENTS AND GENERAL PRACTITIONERS

BY

CHARLES H. MAY, M.D.

Chief of Clinic and Instructor in Ophthalmology, College of Physicians and Surgeons,
Medical Department, Columbia University, New York—1890-1903; Ophthalmic
Surgeon to the City Hospitals, Randall's Island, New York; Consulting
Ophthalmologist to the French Hospital and to the Red Cross
Hospital, New York; Adjunct Ophthalmic Surgeon to
Mt. Sinai Hospital, New York, etc.

Fourth Edition, Revised

WITH 360 ORIGINAL ILLUSTRATIONS
INCLUDING 21 PLATES, WITH 60 COLORED FIGURES

NEW YORK
WILLIAM WOOD AND COMPANY
MDCCCCV

COPYRIGHT, 1905, by
WILLIAM WOOD AND COMPANY.

First Edition, August, 1900.

Second Edition, September, 1901. Reprinted October, 1901, and July, 1902.

Third Edition, August, 1903. Reprinted January, 1904, and October, 1904.

German Translation by Dr. E. Oppenheimer, Hirschwald, Berlin, 1904.

Italian Translation by Prof. E. Trombetta, Union Tipografico, Turin, 1905.

British Edition by Mr. Claud Worth, Ballière, Tindall & Cox, London, 1905.

PREFACE TO THE FOURTH EDITION.

THE third edition of this manual appeared in August, 1903, and has been reprinted twice. In presenting the fourth edition, the author desires to express his appreciation of the continued favor with which his work is received. Every page has been carefully examined and a considerable number of alterations have been made. Many illustrations have been replaced by superior ones. New figures have been added, including eight additional colored plates; among the latter are six presenting twenty-nine colored drawings of external diseases of the eye.

The volume has been kept up to date, but has not been increased in size, the original plan of presenting a book for the student and general practitioner having been adhered to.

CHARLES H. MAY, M.D.

698 MADISON AVENUE, NEW YORK,
August 1, 1905.

PREFACE TO THE FIRST EDITION.

IN the following pages the author has endeavored to present a concise, practical, and systematic Manual of the Diseases of the Eye, intended for the student and the general practitioner of medicine. The great difficulty in preparing a book of this sort is to say enough but not too much. With this idea in view, the author has made the volume sufficiently comprehensive, up to date, and yet of limited size.

This restriction in size has been accomplished by omitting excessive detail, extensive discussion, and lengthy accounts of theories and rare conditions. The author has endeavored to give the fundamental facts of ophthalmology and to cover all

that is essential in this branch of medicine, always keeping in mind that the book has been written for students and general practitioners. Space therefore has been allotted as the necessities of such readers require, estimated by an extended experience in teaching. Thus, rare conditions have merely been mentioned; uncommon affections, of interest chiefly to the specialist, have been dismissed with a few lines; and common diseases, which the general practitioner is most frequently called upon to treat, have been described with comparative fulness.

The book is not recommended as a substitute for the larger works, but as a means of supplying a foundation to which further knowledge may be added by reference to more extensive and comprehensive text-books.

The illustrations, excepting those showing instruments, are original, and have been inserted wherever it seemed that they would be of value in elucidating the text. Those in colors represent the most common changes in the fundus, a knowledge of which is desirable in the treatment of general and nervous diseases as well as in ocular diagnosis, and thus practically supply an ophthalmoscopic atlas.

C. H. M.

CONTENTS.

CHAPTER I.

External Examination of the Eye by Means of Inspection and Palpation.

INSPECTION, 1; PALPATION, 7.

CHAPTER II.

Subjective or Functional Examination of the Eye.

ACUTENESS OF VISION, 9; THE FIELD OF VISION, 13; THE COLOR SENSE, 16; THE LIGHT SENSE, 17.

CHAPTER III.

Objective Examination of the Eye Conducted in the Dark Room. Oblique Illumination and the Ophthalmoscope.

OBLIQUE ILLUMINATION, 18; THE OPHTHALMOSCOPE, 19; THE OPHTHALMOSCOPIC EXAMINATION, 21; THE NORMAL FUNDUS, 31.

CHAPTER IV.

Affections of the Eyelids.

ANATOMY, 35; BLEPHARITIS, 36; HORDEOLUM, 37; CHALAZION, 38; TRICHIASIS, 40; ENTROPION, 41; ECTROPION, 47; PTOSIS, 51; TUMORS, 55; INJURIES, 56.

CHAPTER V.

Diseases of the Lacrymal Apparatus.

ANATOMY, 58; CHRONIC DACRYOCYSTITIS, 60; ACUTE DACRYOCYSTITIS, 65.

CHAPTER VI.

Diseases of the Orbit.

ANATOMY, 68; ORBITAL PERIOSTITIS, 70; ORBITAL CELLULITIS, 72; OPERATIONS UPON THE EYEBALL, 75; ENUCLEATION, 75; EVISCERATION, 77; MULES' OPERATION, 77.

CHAPTER VII.

Diseases of the Conjunctiva.

ANATOMY, 79; ACUTE CATARRHAL CONJUNCTIVITIS, 81; CHRONIC CATARRHAL CONJUNCTIVITIS, 84; FOLLICULAR CONJUNCTIVITIS, 85; GONORRHOEAL OPHTHALMIA, 87; OPHTHALMIA NEONATORUM, 90; DIPHThERITIC CONJUNCTIVITIS, 93; CROUPOUS CONJUNCTIVITIS, 94; GRANULAR CONJUNCTIVITIS, 95; PHYLCTENULAR CONJUNCTIVITIS, 103; SPRING CATARRH, 107; SYMBLEPHARON, 108; PTERYGIUM, 109; INJURIES, 110.

CHAPTER VIII.

Diseases of the Cornea.

ANATOMY, 111; KERATITIS, 112; ULCER OF THE CORNEA, 113; INTERSTITIAL KERATITIS, 122; STAPHYLOMA OF THE CORNEA, 126; KERATOCONUS, 127; OPACITIES OF THE CORNEA, 128; INJURIES, 130.

CHAPTER IX.

Diseases of the Sclera.

ANATOMY, 133; EPISCLERITIS, 134; SCLERITIS, 135; STAPHYLOMA, 136; INJURIES, 136.

CHAPTER X.

Diseases of the Iris.

ANATOMY, 138; IRITIS, 139; INJURIES, 145; THE PUPIL, 146.

CHAPTER XI.

Diseases of the Ciliary Body.

ANATOMY, 149; CYCLITIS, 150; IRIDOCYCLITIS, 150; INJURIES, 152.

CHAPTER XII.

Diseases of the Choroid.

ANATOMY, 153; EXUDATIVE CHOROIDITIS, 153; PURULENT CHOROIDITIS, 157.

CHAPTER XIII.

Diseases of the Whole Uveal Tract. Uveitis.

SYMPATHETIC OPHTHALMITIS, 159; PANOPHTHALMITIS, 162

CHAPTER XIV.

Intraocular Tumors.

SARCOMA OF THE CHOROID, 164; GLIOMA OF THE RETINA, 165.

CHAPTER XV.

Glaucoma.

ANATOMY, 167; ACUTE INFLAMMATORY GLAUCOMA, 169; CHRONIC INFLAMMATORY GLAUCOMA, 173; SIMPLE GLAUCOMA, 173; IRIDECTOMY, 177; SCLEROTOMY, 183; SECONDARY GLAUCOMA, 184; CONGENITAL GLAUCOMA, 184.

CHAPTER XVI.

Diseases of the Vitreous.

ANATOMY, 186; OPACITIES, 187; HEMORRHAGES, 188; FOREIGN BODIES, 188; MAGNET EXTRACTION, 189.

CHAPTER XVII.

Diseases of the Lens.

ANATOMY, 191; CATARACT, 192; SENILE CATARACT, 194; CATARACT EXTRACTION, 199; CONGENITAL CATARACT, 204; TRAUMATIC CATARACT, 205; DISCUSSION OF THE LENS, 205; ANTERIOR POLAR CATARACT, 207; POSTERIOR POLAR CATARACT, 207; ZONULAR CATARACT, 208; COMPLICATED CATARACTS, 209; AFTER-CATARACT, 209; DISLOCATION OF THE LENS, 210.

CHAPTER XVIII.

Diseases of the Retina.

ANATOMY, 213; PHYSIOLOGY, 214; RETINITIS, 215; SIMPLE RETINITIS, 217; ALBUMINURIC RETINITIS, 218; DIABETIC RETINITIS, 220; LEUKÆMIC RETINITIS, 220; SYPHILITIC RETINITIS, 220; HEMORRHAGIC RETINITIS, 221; PURULENT RETINITIS, 221; CIRCULATORY DISTURBANCES, 223; HEMORRHAGES, 223; EMBOLISM, 224; RETINITIS PIGMENTOSA, 226; DETACHMENT, 227.

CHAPTER XIX.

Diseases of the Optic Nerve.

ANATOMY, 230; CONGESTION OF THE OPTIC DISC, 231; PAPILLITIS, 231; ACUTE RETROBULBAR NEURITIS, 234; TOXIC AMBLYOPIA, 235; ATROPHY OF THE OPTIC NERVE, 237.

CHAPTER XX.

Amblyopia and Functional Diseases of the Retina.

AMBLYOPIA, 240; AMAUROSIS, 240; CONGENITAL AMBLYOPIA, 240; HYSTERICAL AMBLYOPIA, 241; SIMULATED AMBLYOPIA, 242; COLOR BLINDNESS, 243; AMBLYOPIA FROM VARIOUS CAUSES, 245; HEMI-ANOPSIA, 247.

CHAPTER XXI.

General Optical Principles.

DISEASES OF THE EYE.

CHAPTER I.

EXTERNAL EXAMINATION OF THE EYE BY MEANS OF INSPECTION AND PALPATION.

Introduction.—Thorough examination of the eye requires the adoption of a certain routine. The history of the patient's complaint will lead the trained observer to concentrate his attention upon the affected part of the eye; but until proficiency is gained through experience it is not safe to depart from a systematic plan of examination.

The eye, being intimately associated with the rest of the body, must not be regarded as an isolated organ. Hence a knowledge of the condition of the system is often valuable in the diagnosis and successful treatment of ocular disease. The parts immediately surrounding the eye must also receive careful attention.

Systematic examination of the eye may be divided into (1) *Objective*, (2) *Subjective* or *functional*.

The *objective examination* may be subdivided into

(a) Examination of the appendages and the anterior portions of the eyeball by means of *inspection and palpation*; this part of the examination is usually conducted in *daylight*.

(b) Examination of the cornea and of the interior of the eyeball in the *dark room*, with *artificial light*, by means of *oblique illumination* and the *ophthalmoscope*.

Inspection.—Those parts of the eye which admit of examination by daylight are best illuminated by seating the patient so that he faces a window. Taking a general survey of the eyes, we notice certain prominent symptoms, such as congestion, discharge, lachrymation, photophobia, etc.

Proceeding from the superficial to the deeper parts, we

commence with the *lids*, noticing their thickness, color, and position; the condition of their margins, whether swollen, crusted, or ulcerated; the power of opening and closing; the size of the palpebral aperture, and the position and permeability of the lacrymal puncta. Then passing to the region of the *tear-sac*, we see whether this is swollen, and whether pressure with the tip of the index finger causes escape of secretion, pointing to disease. We examine the condition and direction of the *cilia*, and notice whether any are misdirected.

FIG. 2.—Eversion of the Lower Lid.

FIG. 3.—First Step in Eversion of the Upper Lid.

Next we inspect the inner or *conjunctival surfaces of the lids*, observing any change in smoothness, thickness, and secretion of this membrane, and looking for foreign bodies.

Exposure of the Conjunctiva of the Lower Lid is easy: Place the thumb near the margin of the lid, press downward, while the patient looks up (Fig. 2).

Eversion of the Upper Lid requires a little practice: Grasp the central lashes between the thumb and index finger of the right hand and draw the lid strongly downward and away from the globe, directing the patient to look down (Fig. 3); place the left thumb (or a probe held horizontally) at the upper margin of the tarsus and press downward, at the same time quickly turning the lid. Having turned the lid, it can be kept everted by shifting the left thumb against the margin,

the other fingers of the left hand being applied to the patient's forehead (Fig. 4).

This exposes the tarsal portion of the conjunctiva. If we wish to inspect the *retrotarsal fold* (and this is important in the examination for trachoma), it is necessary to continue as follows: Press the edge of the everted upper lid firmly against the supraorbital margin with the thumb of the left hand; then

FIG. 4.—Keeping the Upper Lid Everted.

FIG. 5.—Exposure of the Retrotarsal Fold of the Conjunctiva of the Upper Lid.

push the lower lid upward over the cornea with the right index finger, at the same time exerting gentle backward pressure upon the eyeball (Fig. 5).

Next we proceed to the *eyeball* and notice its position in the orbit, whether this is normal or whether the globe is pushed forward (*exophthalmos*) or sunken (*enophthalmos*). Its position in reference to the visual lines should be roughly ascertained. We see whether the visual lines meet at the object looked at, by directing the patient to gaze at a finger held about a foot in front of the eyes; if they deviate, we investigate whether there is loss of motion in any direction (*paralysis*), or absence of muscle-balance, either latent (*heterophoria*) or manifest (*strabismus*), as explained in Chapter XXV.

We observe whether there is any oedema of the bulbar conjunctiva (chemosis), or *congestion* of the anterior part of the eyeball. If the latter is present, it should be examined carefully, for the nature of this injection points to the seat of inflammation (Plate VII).

Following this, the *cornea* is inspected, and may reveal inflammation, ulceration, vascularization, opacities, or foreign bodies. As an aid, we may now use a strong convex lens with which to concentrate the light from the window, but this

FIG. 6.—Placido's Disc.

method (oblique illumination) gives better results in the dark room with artificial light, and is, therefore, described in Chapter III. The *corneal reflex* derived from the window bars gives us information concerning the curvature and smoothness of this part of the eye. Placido's keratoscope (Fig. 6), a target-like disc consisting of alternate black and white circles, may be used. By causing the patient to look in different directions, every part of the surface of the cornea is explored; distortion of the corneal reflection of the circles or of the lines corresponding to the window panes indicates a change of curvature or roughness. A minute foreign body can often be detected in this manner (Fig. 7).

To bring an abrasion, infiltration, or ulcer of the cornea more clearly into view, we may instil a drop of two-per-cent. solution of *fluorescein*, washing off the excess with water. Wherever the corneal epithelium is absent there will be a green stain.

We often find evidences of previous ulceration of the cornea in the form of *opacities*. When a corneal opacity is very faint and cloud-like, it is called a *nebula*; when denser, a *macula*; and when perfectly opaque and white, a *leucoma* (Figs. 138, 139, 140).

The *sensitiveness* of the cornea may be noted by touching it

FIG. 7.—Corneal Reflection of Placido's Disc. A, Normal; B, distortion caused by foreign body on the cornea.

gently with a thread or piece of soft paper, taking care not to touch the lids or lashes.

When there is much irritation, spasm of the lids (*blepharospasm*) prevents a proper examination. In such cases, the instillation of a solution of cocaine or holocain will aid us in exposing the eyeball.

In infants or very young children, when blepharospasm,

FIG. 8.—Method of Examining the Eyes of Infants and Young Children.

swelling, inflammation, or obstinacy prevents us from inspecting the cornea in the usual way, the child is laid upon its back across the nurse's lap, its hands are held, and its head is steadied between the knees of the examiner (Fig. 8). Under such circumstances the lids may usually be everted by pulling upon them at a little distance from the margin. To inspect the eyeball, we part the lids by placing our thumbs at the edges, rolling in the latter somewhat and then separating, keeping close to the surface of the eyeball (Fig. 9). Having

exposed the eyeball, we may replace the thumb of the right hand by the index finger of the left, thus leaving the right

FIG. 9.—Method of Exposing the Eyeball.

hand free for other uses. The eye will usually be found turned upward, hence the cornea will be hidden from view; but after a minute it will appear in the palpebral aperture. Care must be taken not to scrape the cornea and cause an abrasion, nor to exert any pressure upon the eyeball, on account of the danger of perforation in case the cornea has become weakened by ulceration.

It is sometimes necessary to use *retractors* (Fig. 10) in order to separate the lids under such circumstances, and with these the same caution is required against wounding the cornea or pressing upon the eyeball. If this procedure should prove unsatisfactory, a general anæsthetic must be employed. When forcibly separating the lids we must remember that pent-up secretions are released suddenly and may squirt into the eyes of the examiner.

Next we examine the *anterior chamber* and note its depth, whether normal, shallow, or increased, and whether the *aqueous humor* is clear; if the latter is altered, we observe whether the exudation consists of pus (*hypopyon*), blood (*hyphæma*), spongy exudation, or the like.

The *iris* comes next. We note its color, smoothness, and thickness, whether its markings are clearly defined or blurred, and whether it is steady or tremulous during movements of the eyeball. *Adhesions* to the cornea (*anterior synechiæ*) or to the capsule of the lens (*posterior synechiæ*) are looked for. These usually require the instillation of a mydriatic for their detection.

FIG. 10.—Lid Retractor.

Then we note the characteristics of the *pupil*: size, shape,

and position; also its reaction to light, and in accommodation and convergence as explained on page 147. Behind the pupil we see the central part of the anterior surface of the *lens* and observe its transparency or any abnormal condition which may be present, such as cataract and deposits. To explore the lens fully, dilatation of the pupil and artificial illumination are required.

Palpation gives us information regarding (1) the presence or absence of *sensitiveness in the ciliary region*, (2) the degree

FIG. 11.—Testing the Tension of the Eyeball.

of *hardness of the eyeball*, and (3) the existence of *tumors and swellings* in and about the orbit.

Ciliary Tenderness.—By exerting gentle pressure upon the sclera, just behind the cornea (Fig. 11), as described below, we may discover ~~increased~~ sensitiveness of the ciliary body; this is an important symptom of cyclitis.

Eyeball Tension.—To ascertain the tension, we direct the patient to look down, and then gently palpate the sclera above the cornea, by means of the two index fingers placed upon the

upper lid (Fig. 11), just as in feeling for fluctuation in an abscess. We estimate the degree of tension by comparison with the other eye, if normal, or with another healthy eye. Instruments have been devised for this purpose, but such tonometers are rarely used. *Increase of tension* is a prominent symptom of glaucoma; perforating wounds and degenerated conditions of the eyeball cause *diminished tension*; alternations in tension are sometimes found in cyclitis.

Tension is *expressed* by the sign T. followed by n. when normal, by + or - when increased or diminished, with numerals indicating the degree of change, as follows:

T.n. = Tension normal.

T. + = Tension increased.

T. - = Tension diminished.

T. + 1 = Appreciable hardness.

T. - 1 = Appreciable softness.

T. + 2 = Decided hardness.

T. - 2 = Decided softness.

T. + 3 = Board-like hardness.

T. - 3 = Eyeball very soft.

Thus we conduct that portion of the objective examination for which daylight furnishes suitable illumination. For more minute inspection of the cornea, anterior chamber, iris, and lens, as well as for examination of the vitreous and fundus, we resort to oblique illumination and the use of the ophthalmoscope in the dark room (Chapter III.).

CHAPTER II.

SUBJECTIVE OR FUNCTIONAL EXAMINATION OF THE EYE.

THE subjective examination, dependent upon the statements of the patient, comprises the testing of the function (vision or sight) of each eye separately. This function may be subdivided into (1) the form sense; (2) the color sense; and (3) the light sense.

The *form sense* is the faculty which the eye possesses of perceiving the shape or form of objects, and is expressed as *acuteness of vision*. The *color sense* is the power which the eye has of distinguishing light of different wave lengths, *i.e.*, distinguishing colors. The *light sense* is the faculty of perceiving different degrees of intensity of illumination (brightness). We distinguish between *central and peripheral vision*.

THE ACUTENESS OF VISION.

Central or Direct Vision.—When we wish to obtain a distinct image, we look directly at an object so that the image falls upon the macula lutea, the portion of the retina which is adapted for the most acute vision. The acuteness is tested both for *distant* and for *near* vision.

Distant Vision.—In testing for distance a range of 20 feet (6 metres) is selected, since rays of light from this distance are practically parallel. For this purpose we make use of *Snellen's test types*, which are constructed upon the following principle: Each letter is inscribed within a square (Fig. 12) which subtends a visual angle of 5' at the distance at which the normal eye should distinguish the letter. The visual angle is included between two lines drawn from the extremities of the object through the nodal point of the eye (Fig. 13). Each side of the square is subdivided into five equal

parts; the smaller squares thus formed subtend a visual angle of $1'$, which is the minimum visual angle for the normal eye—

FIG. 12.—Construction of Snellen's Test Types.

that is, if two black objects on a white ground are separated by a space subtending a smaller angle, they will no longer be seen separate. In order to subtend the same visual angle, the size of the letters must increase the farther they are removed from the eye (Fig. 13).

Snellen's Test Types consist of square-shaped letters arranged upon a chart, the size of the letters diminishing from above downward. The height of each letter subtends a visual angle of $5'$, the width of the component limbs a visual angle of $1'$. The uppermost letter is of such

FIG. 13.—The Estimation of the Size of Snellen's Test Types at Various Distances.

a size that it can be read at 200 feet; then follow rows of letters which should be read at 100, 70, 50, 40, 30, 20, 15 and 10 feet respectively (Figs. 14 and 15).

The acuteness of vision is expressed by a *fraction*, the numerator of which corresponds to the number of feet separating the patient from the chart (preferably 20 feet), and the denominator to the number indicating the distance at which the smallest letters seen should be read by the normal eye. If the patient's sight is normal, his acuteness of vision will equal $\frac{20}{20}$; this is expressed $V. = \frac{20}{20}$. If he can see only the third line from the top, $V. = \frac{20}{70}$. If he cannot read more than the top letter, $V. = \frac{20}{200}$. If he reads some letters in the 50 line, but not all of this size, $V. = \frac{20}{50}$ — or $\frac{20}{70} +$. Many persons, especially during youth, can read the line which should be read at 15 feet, or even 10 feet, when placed 20

feet from the chart; the fractions in these cases would be $\frac{20}{15}$ and $\frac{20}{10}$.

If the patient's vision is less than $\frac{20}{200}$, we reduce the distance from the chart. If he sees the largest letter at 8 feet, $V. = \frac{8}{200}$. If he cannot read the top letter at any distance, we record the distance in feet or inches at which he can correctly count the examiner's fingers held against a dark

FIG. 14.—Snellen's Test Types. Usual Style of Chart.

FIG. 15.—Snellen's Test Types. White Letters on a Black Ground.

FIG. 16.—Test Types for Illiterates.

background; for example, $V. =$ Fingers at one foot or $V. =$ Fingers at 7 inches. If he has less sight than this, we move the hand before the eye, and if he is capable of appreciating such movements, we say he has "*perception of hand movements.*" If his vision is still further reduced, we ascertain whether he has *preception of light* (P. L.) by alternately shading and exposing the eye. This is done by means of the hand, or by throwing light upon the eye with the ophthalmo-

scopic mirror in the dark room, and noting whether he indicates the presence or absence of illumination.

Each eye is tested separately, one eye being covered with a card, or with the opaque disc supported in the trial frame. Daylight is the usual means of illuminating the chart, but

No. 1.

*Engaged in manual occupation of a coarser sort, the laborer has little opportunity either to try or to misuse his organ of vision; his sight, unless attacked by local inflam-

tion in eyesight and changes in the form, and hence in the dioptric

FIG. 17.—Jaeger's Test Types for Near Vision.

artificial light thrown directly upon the test letters may be used.

The test types are hung opposite a window, at about the level of the patient's eyes, and the patient is placed with his back to the source of illumination.

When the person is *illiterate*, we employ a series of letters E, with sizes corresponding to those of the Snellen types, in which the openings point downward, upward and to the right and left (Fig. 16); the acuteness of vision is then fixed by the smallest row of which the patient can correctly tell the direction in which the figures are open.

Near Vision.—When in a state of rest, the eye is adapted for parallel rays coming from a distant object. In order that divergent rays from a near object shall be focussed on the retina, there must be an increase in the refractive power of the eye; this change is known as *accommodation*;

it will be more fully described in Chapter XXII.

The test types usually employed to determine near vision consist of different sizes of ordinary printer's types; the finest is numbered 1, successive numbers indicating coarser type. They are known as *Jaeger's test types* (Fig. 17).

The patient should be placed with his back to the light, so

that the page is well illuminated, and each eye tested separately. His near vision is expressed by J., followed by the number corresponding to the finest print which he can read; thus, J. 3 means that the patient is able to read the third paragraph.

THE FIELD OF VISION.

Peripheral Vision is exercised when the image falls upon some part of the retina outside the fovea centralis; such vision is indistinct, but of great importance.

The Field of Vision represents the limits of peripheral or indirect vision; it is the space within which an object can be seen while the eye remains fixed upon some one point. It usually refers to one eye, the other being covered, and, when not otherwise stated, applies to a white object. The field can be outlined roughly by the hand, more accurately by a piece of chalk upon a blackboard, or a lighted candle, most exactly by means of a perimeter.

The Hand Test.—The patient is turned with his back to the light, and the examiner faces him at a distance of two feet. After covering one eye, the patient is directed to fix that eye of the examiner, which is opposite; the examiner closes his other eye. The hand with extended fingers is then moved from various parts of the periphery inward, midway between examiner and patient, and the latter indicates when he sees the fingers. In this way the examiner can compare the patient's field with his own; if both be normal, patient and examiner must see the fingers simultaneously. This is a very simple and rapid method, and will reveal any large defect in the field. Instead of the hand, a small white knob upon the end of a rod may be used to measure the field.

The Candle Test.—When the patient is no longer able to see the hand, we make use of a lighted candle, in the same manner, in the dark room; or the light may be reflected from an ophthalmoscopic mirror.

The Blackboard Test gives us an approximately correct graphic representation. The patient is placed 12 inches in front of a blackboard, upon which we mark a cross to serve as

the point of fixation. A piece of chalk is now gradually brought from the periphery toward the centre, and the patient indicates when he sees it in the several directions. These points are marked, and by connecting them an outline of the field is obtained.

The Perimeter (Fig. 18) furnishes the most exact method. It consists of a metallic semicircle or quadrant, which can be

FIG. 18.—The Perimeter.

revolved so as to take the direction of any meridian. This arc is marked in degrees, 0 corresponding to the middle point and 90 to either extremity. The patient's head is supported upon a chin-rest, one eye covered, and the other fixed upon an object placed at the centre of the arc. The test object, a piece of white paper

10 mm. square, is carried along the inner surface of the arc; and the points where it is first seen in the different principal meridians are marked upon diagrams of the normal field; the lines connecting these form the boundary of the field.

Extent of the Normal Field of Vision.—Toward the temporal side it is 90° (or over); in other directions it is less extensive, on account of the more anterior termination of the pericipient layers of the retina on the nasal side. On the nasal side the field extends 60°; above, 60°; below, 70° (Fig. 19).

Pathological Alterations in the Field of Vision.—These consist of *limitation* and *defects*. Limitations may assume the form of contraction evenly in all directions (*concentric*), *irregular* contraction (Fig. 175), or loss of part of the field on *one side* or the other.

Concentric contraction affects all parts of the periphery alike; when considerable, nothing but central vision may remain

(Fig. 229); such contraction with preservation of good central vision is met with especially in retinitis pigmentosa. The contraction may affect only one side of the periphery; in such cases we speak of temporal or nasal contraction, or upper or

FIG. 19.—Normal Fields for White and for Colors (Blue, Red, and Green).

lower contraction. When one-half of the field is absent (Fig. 234), it constitutes *hemianopsia* (p. 249). *Sector-shaped* contractions sometimes exist; the defect then has the shape of a triangle the base of which is peripheral. Certain affections produce characteristic contraction of the visual field; for instance, in atrophy of the optic nerve the contraction is concentric; in glaucoma, it is usually greatest on the nasal side.

A *scotoma* is a defect within the visual field. A physiological scotoma is the blind spot, the situation of which is about 15° to the outside of the point of fixation, corresponding to the entrance of the optic nerve (the black spot in Fig. 19). According to their situation, we divide scotomata into *central* and *peripheral*. A *central scotoma* corresponds to the point of fixation (Fig. 228); when marked, it interferes with or abol-

ishes central vision altogether; the scotoma accompanying hemorrhage at the macula furnishes an example. *Peripheral scotomata* cause little disturbance of sight and may exist without the patient's knowledge, especially when situated far from the point of fixation; disseminated choroiditis furnishes examples of scotomata of this sort (Fig. 162).

Scotomata may be *positive*, when the patient sees them as black spots in his field, or *negative*, when they exist as defects in the visual field, but are not perceived by the patient until the visual field is examined. Positive scotomata are due to changes in the media or in the retina. If the opacities exist in the vitreous, the scotomata are *motile*; *muscae volitantes* represent one variety of defects of this sort. Negative scotomata may be *absolute*, when perception of light is entirely lost over the defective area, or *relative*, when there is only diminished perception of light, or loss of perception of certain colors over this area. Toxic amblyopia gives us an example of a scotoma which is central, relative, and often negative. For the detection of scotomata, test objects having a diameter of from 2 to 5 mm. should be used.

THE COLOR SENSE.

The color sense as a whole (*i.e.*, the faculty of distinguishing different colors) is investigated by the methods described in Chapter XX. We distinguish between *central* and *peripheral perception of color*. The former is tested by the exhibition of samples of colored wool as described on page 244, the latter by small objects, such as squares of colored paper or small colored knobs 5 to 10 mm. in diameter, which are moved from the periphery toward the centre, on the perimeter or in the coarser methods of testing the field.

The Field for Colors is smaller than that for white, but has the same general shape. It varies also for different colors; that for blue is the largest, next comes red, while green has the smallest field. The limits (given in Fig. 19) correspond to the points at which the colors are recognized, not to those points at which merely the presence of a moving object is per-

ceived. The examination of the color fields is of *considerable importance*, since we frequently find that contraction of the field for colors exists at an earlier period than that for white. It is a more delicate test, and detects diminution of visual power before it has become sufficiently pronounced to affect the field for white.

THE LIGHT SENSE.

The power of perceiving gradations in intensity of illumination (brightness) is tested by means of instruments known as photometers. We determine either the *smallest degree of light* with which an object is still visible, or the *smallest difference in illumination* which can be appreciated. The estimation of the light sense has not yet found practical utilization in ophthalmology; but experiments seem to indicate that it may before long be of advantage in diagnosis. Diminution in the light sense is not always proportionate to changes in the acuteness of vision. Marked reduction of the light sense is seen in cases which are accompanied by night blindness (hemeralopia)—retinitis pigmentosa, for instance.

The examination of the *motility of the eye* is described in Chapter XXV.

CHAPTER III.

OBJECTIVE EXAMINATION OF THE EYE CONDUCTED IN THE DARK ROOM: OBLIQUE ILLUMINATION AND THE OPHTHALMOSCOPE.

The Examination in the Dark Room comprises the following steps, which are best taken in the order given:

1. *Oblique illumination*, for the physical examination of the anterior portions of the eyeball.

2. *Examination with the ophthalmoscope at a distance*, for exploring all the media of the eyeball.

3. *The indirect method of ophthalmoscopy*, for examining the fundus, giving an inverted picture of low magnification.

4. *The direct method of ophthalmoscopy*, for examining the fundus, giving an erect picture of greater magnification.

The examining-room should have dark walls and all light excepting that made use of by the surgeon should be excluded. The source of illumination usually preferred is an Argand gas burner, or an electric light with frosted globe, upon a "*universal bracket*," which permits the flame to be placed on either side of the patient, and to be raised or lowered at will. Patient and examiner may be either standing or seated.

OBLIQUE ILLUMINATION.

Oblique, *lateral*, or *focal illumination* furnishes a very valuable means of minutely exploring the *cornea*, *anterior chamber*, *iris*, and *lens*. By means of a *strong convex lens* of two- or three-inch focus, light is concentrated upon the eye in such a manner that the apex of the cone of light corresponds to the part to be examined (Fig. 20). The source of illumination should be about eighteen inches to the side of the patient, several inches in advance, and on a level with the eye. The lens is grasped by its margin between the thumb and

index finger, held so that its surfaces are at right angles to the direction from which the light proceeds, and steadied by means of the little finger placed against the side of the patient's face. After having examined one eye, without removing the supporting finger, we turn the patient's head slightly toward the light and illuminate the other eye. The flame may be placed on either side; if on the patient's right, we use the left hand for holding the lens; if on the left, we use the right hand. After having examined the cornea the lens is brought

FIG. 20.—Oblique Illumination.

nearer to the eye, so that the apex of the cone of light corresponds to the deeper structures which we wish to explore.

With a second strong convex lens held at its focal distance (two or three inches) in front of the patient's eye, we can magnify the illuminated area and thus obtain greater detail.

Opacities of the cornea, aqueous, or lens, seen by oblique illumination, appear as *grayish* or white *spots* upon the *black ground* of the pupil (Figs. 25, 27, 29, 31, Plate II).

THE OPHTHALMOSCOPE.

The ophthalmoscope (Fig. 21) was invented by Helmholtz in 1851. Previous to this period we had practically no knowl-

edge of the interior of the eye during life. The essential portion of this instrument is a *perforated mirror*. This is mounted upon a convenient handle and supplemented behind by a disc containing convex and concave lenses. The mirror serves to reflect light into the interior of the eye, while the aperture allows a portion of this light, after returning from the patient's eye, to pass into that of the observer. The mir-

FIG. 21.—The Author's Ophthalmoscope.
A, Mirror side; B, Lens disc; C, Rear side,

FIG. 22. — Electric
Ophthalmoscope.
Author's Model.

ror commonly employed is concave, of about ten inches focus, either circular or of the form of a parallelogram, which allows it to be tilted to the right or left. The *lens disc* is placed behind the mirror and provided with a collection of lenses, which follow each other in regular order from the weaker to the stronger. By means of the finger applied to a milled edge the disc can be rotated so that any lens is placed behind the perforation in the mirror. Opposite each lens is a number indicating its strength in diopters and in inches. In instruments of American manufacture the convex or + lenses are usually marked in white, the concave or — lenses in red.

The *Electric Ophthalmoscope* (Fig. 22) is self-illuminating, the lighting current being usually supplied by a small portable storage battery. It is very convenient for bedside use, since the patient can readily be examined in any position and no specially darkened room is necessary.

THE OPHTHALMOSCOPIC EXAMINATION.

Before attempting to see the *fundus*, we must explore the *media*. This preliminary step is important, since it will explain modifications in the picture obtained by subsequent methods, or failure to see the fundus in cases in which changes in the media exist. One mode of obtaining such information, oblique illumination, has already been described; it is particularly applicable to the anterior media. A second method is

Examination with the Ophthalmoscope at a Distance.—This method explores *all the media*—cornea, aqueous, lens, and vitreous. The light is reflected from the mirror into the eye, and, returning from the background, traverses the media before reaching the eye of the examiner through the aperture in the mirror.

The source of illumination is placed on either side of the patient, on a level with the eye and several inches to the side and behind, so that the light strikes the patient's temple, leaving his face in darkness. The patient faces the examiner, the latter standing or sitting directly in front. The ophthalmoscope is held in front of either eye of the observer, so that he can look through the perforation, and is steadied against the side of the nose and supraorbital margin. The distance between patient and examiner is about *fifteen inches*.

From the mirror the light is reflected into the eye of the patient. Reaching the background, it is *colored* orange-red by contact with the choroidal vessels and retinal and choroidal pigment. This tinted light returns through the patient's eye and enters the eye of the examiner by means of the aperture in the mirror. The *exact tint varies* with the color of the background of the individual, depending upon the abundance

of choroidal and retinal pigment; hence it is brighter in persons of light complexion, and darker in others. It is also influenced by the amount of illumination, and consequently the reflex is brighter when the pupil has been artificially dilated. The patient is told to move the eyes in various directions, and in this manner all parts of the media are explored.

In the normal eye a *homogeneous orange-red reflex* (*fundus reflex*) is obtained (Fig. 23, Plate II). If any details of the vessels of the fundus are seen, the eye is ametropic (Fig. 24, Plate II). If, when the observer moves his head from side to side, these vessels appear to move in the same direction, the eye is hyperopic; if in the opposite direction, it is myopic.

If *opacities* exist in any of the media, they will appear as *dark* or *black spots* upon the colored background of the pupil. They are dark because they intercept a certain part of the light (Figs. 26, 28, 30, 32, Plate II). Opacities of the media may be either *fixed*, in which case they move only with the eye, or *movable* (floating), when they float about after the eye has been rapidly moved and then suddenly stopped; the latter occur only in the vitreous.

The exact *situation of opacities* of the media can often be estimated by oblique illumination. Another method consists in noting the *displacement* of the opacity *with regard to the pupil*, when the observer's head is moved slowly from side to side. When there is no apparent motion of the opacity, it is in the plane of the iris; when it appears to move in the opposite direction, it is in front; and when in the same direction, it is behind this plane. A third method is based upon the *relationship of the motion* of the opacity to that of the *eyeball*. If, when the patient moves his eye, the opacity moves with (in the same direction as) the eye, it must be in front of the centre of rotation of the globe (which corresponds to the anterior portion of the vitreous, about 10 mm. in front of the retina); if it moves in the opposite direction, it must be behind this point; if it has no motion, it must be exactly at the centre. In both of these tests the greater the apparent

motion the more removed is the opacity from the plane of the iris and the centre of rotation of the globe respectively.

Additional detail of changes in the media and iris may be obtained by placing *strong convex lenses* (from 5 to 20 D.) in the sight-hole of the ophthalmoscope, gradually approaching the eye as the strength of the lenses is increased.

Having ascertained the condition of the media, we proceed to *examine the fundus*. The expert may succeed with a pupil of natural size; but it is often wise, and not infrequently necessary, to *dilate the pupil*. Moderate dilatation is secured by instilling one drop of a four-per-cent. solution of *cocaine*; after 15 minutes the pupil will be of sufficient size, and the effects will pass off in half an hour, thus causing no discomfort to the patient. A five-per-cent. solution of *euphthalmin* acts more energetically, and the effects pass off within a few hours. Greater dilatation follows the instillation of one drop of a two-per-cent. solution of *homatropine*, or of a mixture of two per cent. homatropine and one per cent. cocaine; these cause mydriasis in from 20 to 30 minutes, and the effects last from 24 to 36 hours.

There are *two methods of examining the fundus*: (1) the *indirect*, (2) the *direct*.

The Indirect Method of Ophthalmoscopic Examination.—With the indirect method we obtain an *inverted image* of the fundus, *magnified about four diameters*. The source of illumination is in the same position as when we examine the media—behind, to the side, and on a level with the eye—and the examiner and patient retain the same relative positions. In the aperture of the ophthalmoscope we place a *3 or 4 D. convex lens*, which enables the examiner to obtain a clear image with his accommodation at rest. Placing the ophthalmoscope before either eye, at a distance of about 15 inches from the patient, we obtain the fundus reflex. A strong convex lens of about two inches focus (called the *objective lens*) is now held at about its focal distance in front of the eye to be examined. This lens is grasped at its edges by the thumb and index finger of the left hand and steadied by placing one of the other fingers against the forehead of the

patient (Fig. 33). If a clear view of some part of the background is not obtained, we vary the distance from the patient by slowly moving the head backward or forward, until there appears a distinct aerial, inverted image of the fundus at a short distance in front of the lens, corresponding to its focus.

After having seen the right fundus, we proceed to the examination of the left, without making any change in the position of the light, ophthalmoscope, patient, or examiner.

FIG. 33.—Indirect Method of Ophthalmoscopic Examination.

We merely move the lens so as to cover the patient's left eye, now steadying it with the middle finger placed upon the forehead; the little and ring fingers are flexed into the palm of the hand, so that they will not obstruct the right or free eye of the patient and thus prevent him from gazing in any direction which we indicate. In the examination of the left eye we may, if we prefer, hold the ophthalmoscope in the left hand and the lens in the right.

We always begin the examination by looking for the *entrance of the optic nerve* (the disc or papilla), this being the most prominent feature of the background. The optic-nerve entrance is a little to the inner or nasal side of the visual axis; hence, in order to bring it into view, it is necessary to direct the patient to *move the eye in* somewhat, which will rotate the

posterior pole of the eyeball outward. When we are directly in front of the patient, this is accomplished by causing him to look *over* our right *shoulder*, on a level with the upper border of the ear, when we examine the right eye, and over our left shoulder on a corresponding level, when we examine the left eye.

To see the *parts surrounding the disc*, we move the lens or the head slightly in various directions, always remembering that the image is inverted, and that it moves with the lens, but in the opposite direction to that taken by the head. More peripheral parts are brought into view when the patient moves his eye up, down, to the right, and to the left.

When the patient looks directly at the ophthalmoscope, it brings the *macula* into view; but since he must accommodate when fixing so near an object, the pupil will contract. On this account it is well to dilate the pupil when we wish to get a view of the macular region with the indirect method.

The beginner may encounter a number of *difficulties* in using the indirect method. He may have trouble in bringing the disc into view, because the patient persists in watching the ophthalmoscope instead of looking across the examiner's shoulder. Owing to defects in the manufacture of the instrument, there are often very *confusing reflexes* from the margins of the sight-hole and perforation of the mirror. There is frequently a very *annoying reflection* of the flame from the cornea or from the surfaces of the lens which we hold before the patient's eye. These reflexes may be obviated by a slight inclination of the lens, a change in the angle of the mirror, or a little variation in the position of the examiner or source of illumination, which experience alone will teach us.

The Direct Method of Ophthalmoscopic Examination.—With the direct method we obtain an *erect* picture of the fundus *magnified about fourteen diameters*.

The examiner sits or stands to the side of and facing the patient (Fig. 34). The ophthalmoscope is supported as in previous methods, and brought directly in front of the patient's eye *as close as possible*. There should not be a greater distance than an inch between the eye of the patient and that

of the observer. The light occupies about the same position as in previous methods.

When we examine the *right eye*, the examiner and the light must be on the *right side*, and consequently the ophthalmoscope must be placed before the right eye of the observer. When the left eye is being examined, the light and examiner must be to the left, and the observer must use his left eye.

FIG. 34.—Direct Method of Ophthalmoscopic Examination.

When the ophthalmoscope is provided with a tilting mirror, the surface of the latter must be turned toward the source of illumination.

When both examiner and patient are *emmetropic*, and both relax their accommodation, the observer looks through the sight-hole and obtains a *clear view* of the fundus without any lens. The patient is told to look at the opposite wall, directly forward, over the shoulder of the examiner. This brings the *disc* into view. The parts around the disc are next examined. The periphery of the fundus is brought into view when the patient looks in various directions. The *macular region* is

found to the outer side of the disc, the distance corresponding to about twice the diameter of the papilla. When the pupil has been artificially dilated so that it cannot contract in accommodation, the macula can also be brought into view by directing the patient to look into the aperture of the mirror.

The *size* of any particular lesion is *compared with* that of the *disc*. Changes in the level of the fundus (elevations, depressions, new growths) are measured in diopters; an elevation of 1 mm. corresponds to 3 D.

The beginner is often annoyed by *reflexes* from the cornea and from the margins of the sight-hole and mirror perforation. The former can be obviated by a slight change in the angle of the mirror, the position of the examiner or that of the light; the latter are due to defects in the ophthalmoscope.

If the observer be ametropic, he must either wear his correcting distance glasses or have a special correcting lens fitted behind the aperture, or he may rotate his correcting lens before the aperture from one of those contained in the disc of the instrument. *When the patient is ametropic*, a suitable lens must be rotated into place behind the aperture; if he is myopic, this will be the weakest concave lens, and if hyperopic, the strongest convex lens, which will give a distinct picture. This gives an indication of the manner in which the direct method is employed for the estimation of errors of refraction.

The emmetropic observer will be unable to obtain a distinct view of the fundus of a myopic eye, by the direct method, without inserting a concave lens. He can examine a hyperopic eye either by putting up a convex lens or by using his accommodation. But in the direct method the observer must learn to *relax his accommodation*. The beginner often finds this difficult, since he cannot forget that he is looking at a very near object, and he accommodates accordingly. He is very apt to place a concave lens of about 4 D. in the sight-hole to neutralize the effects of such efforts, even though the patient has no myopia. Relaxation of accommodation is absolutely indispensable in using the direct method for the purpose of estimating errors of refraction. It is encouraged by *keeping both eyes open* and looking in the distance with the

uncovered eye. The sensation of relaxing the accommodation is experienced when we hold a book at the usual reading distance and stare at the print until it becomes blurred and fades. Such an exercise may be used to cultivate the habit.

The Indirect and Direct Methods Contrasted.—The *indirect method* gives us a *larger field*, though a *smaller magnification*, and hence presents a *general view* of the background, which is

The Direct and Indirect Methods of Ophthalmoscopy Contrasted. The Picture of the Fundus Obtained by the Direct Method (to the Left) is Erect and Highly Magnified. That Obtained by the Indirect Method (to the Right) is Inverted and Less Magnified.

inverted. It can be used successfully independent of errors of refraction in the patient's eye. On account of greater illumination we are often able to get details of the fundus, even when slight opacities of the media exist.

The *direct method*, on the other hand, gives us an *erect picture*, which is more *highly magnified*, though a smaller portion of the field is seen at a time; hence it permits of more *minute exploration* of particular parts to which our attention has been directed by the indirect method. It is also the method of using the ophthalmoscope for the estimation of errors of refraction.

Theory of the Ophthalmoscope.—As ordinarily seen, the pupil appears black because the light which leaves it is necessarily reflected in the direction from which it came. If the eye of the observer be placed so as to intercept the returning rays, the interior of the observed eye will appear illuminated. With the ophthalmoscope light is reflected into an eye under examination, and the observer's eye is placed in the path of the returning rays and receives some of these through the perforation in the mirror.

Fig. 35 explains the illumination of the interior of the eye with the *ophthalmoscope at a distance*. E represents the eye

FIG. 35.—Ophthalmoscopic Examination at a Distance.

of the examiner and P that of the patient. Divergent rays of light, proceeding from the Argand burner L, strike the ophthalmoscopic mirror O, are reflected and made convergent, passing into the eye P, crossing in the vitreous, and illuminating the fundus between A and B. From any point of this illuminated area, C for instance, rays are reflected, pass out of the eye, being made parallel by its refracting apparatus, and proceeding, pass through the aperture of the mirror O into the eye of the examiner E. The dioptric apparatus of E brings these rays to a focus on the retina, and they form at C' an image of C.

Fig. 36 explains the *indirect method*. From L divergent rays proceed to the mirror O, are reflected and made convergent, passing into the examined eye P, crossing in the

vitreous. They illuminate the fundus between A and B. From any portion of this illuminated area, C D for instance, rays are reflected, and, passing out of the eye, are rendered

FIG. 36.—Indirect Method of Ophthalmoscopic Examination.

parallel by its refracting apparatus. They fall upon the convex lens (L) and are brought to a focus $A' B'$, forming an enlarged, inverted image in the air at the focus of the lens (L), which image can be seen by the eye of the examiner, E.

Fig. 37 illustrates the *direct method*. Divergent rays proceeding from L to the mirror O are reflected and made conver-

dioptric apparatus, through the perforation of the mirror O, into the eye of the examiner E. Here they are brought to a focus on the retina. They are convergent, and being prolonged backward, form a magnified and erect image of C D, behind the eye of the patient P, at C' D'.

The Normal Fundus.—The normal fundus exhibits a great many *variations* in details. It presents an *orange-red* surface, upon which we distinguish the *disc*, the *blood-vessels*, and the *macula* (Plates III, IV, V).

The Disc (*Papilla*) represents the *entrance of the optic nerve*; it is usually circular, but sometimes oval in form. Its color is light pinkish, more pronounced over the inner half, the outer portion being paler. The disc is much lighter in color than the rest of the fundus, and is separated from adjacent portions by a *sharply defined margin*, especially at the outer side. This margin often presents two *rings*; an inner, the *scleral* (*s*, Fig. 40), of white color, formed by exposure of the sclera when the opening in the choroid is larger than that in the sclera, and an external ring, the *choroidal* (*c*, Fig.

FIG. 40.—Ophthalmoscopic View and Longitudinal Section of the Disc. *a*, Central artery; *v*, central vein; *E*, physiological excavation; *s*, scleral ring; *c*, choroidal ring; *r*, retina; *ch*, choroid; *scl*, sclera.

40), of dark color, formed by an accumulation of pigment at the margin of the aperture through which the optic nerve passes. This pigmented ring may be complete or incomplete. In the latter case it is generally found at the outer border. The margins of the normal disc are occasionally slightly indistinct, especially above and below. This appearance is sometimes seen in hyperopic eyes of young subjects, and must not be mistaken for neuritis.

The centre of the papilla presents a funnel-shaped depres-

sion (E, Fig. 40, Fig. 43, Plate V) formed by the separation of the nerve fibres. This appears whiter than the rest of the disc. It is known as the *physiological depression* or *cup*. It may be comparatively large and occupy one-half or more of the disc, but never the entire papilla, in which respect it differs from the pathological excavations of glaucoma and of optic-nerve atrophy (Figs. 176, 177, 178). At the bottom of this physiological excavation, when marked, we frequently see grayish spots. These represent the openings in the lamina cribrosa, the connective-tissue layer through which the fibres of the optic nerve pass (Fig. 43, Plate V).

The Central Artery and Vein of the optic nerve (*a* and *v*, Fig. 40) pass along the inner wall of the excavation, and upon reaching the surface of the disc usually divide into *superior and inferior branches*; each of these soon divides and subdivides, giving off *nasal and temporal branches*; from these, smaller twigs are derived which become terminal and do not anastomose. Small branches are often given off from the main trunks and pass across the disc. The macular region is devoid of larger vessels, though finer branches are seen to approach this area. The *arteries* are readily distinguished from the veins by their smaller calibre, bright red color, and straighter course. They present a bright reflex running along the centre. The *veins* are of greater thickness, of a darker red color, more tortuous, and the light streak is fainter. Arteries and veins usually follow the same course. The veins sometimes present a distinct *pulsation*, most marked where the central trunk appears on the disc, and increased by pressure upon the eyeball; this is physiological. Pulsation in the retinal arteries, on the other hand, is pathological, and occurs in glaucoma, cardiac disease, and in profound anæmia.

The Retina itself is *transparent*. The *color of the background* is derived from the choroidal vessels, and modified by the pigment-epithelium layer of the retina and the pigment of the choroid. It is bright orange-red in persons of fair complexion, while in darker individuals it has a deeper, brick-red color. The fundus presents a granular or *stippled* appearance,

PLATE IV.

FIG. 42.—Opaque Nerve Fibres.

PLATE V.

FIG. 43.—Physiological Excavation of the Disc (Direct Method of Ophthalmoscopy).

FIG. 44.—The Region of the Macula Lutea (Direct Method of Ophthalmoscopy).

caused by the pigment cells. When the pigment-epithelium layer of the retina is well developed, the choroidal vessels cannot be seen. More often, considerable detail of the *vessels of the choroid* will be visible. This occurs under two conditions: In some cases there is no obscuration by the pigment layer of the retina, and the choroidal pigment is very abundant and collected into the intervascular spaces; then these stand out as dark islands separating bright-red lines and bands, which anastomose freely, the choroidal vessels (Fig. 41, Plate IV). In other instances there is very little pigmentation in either retina or choroid, allowing the choroidal vessels to be seen plainly, now presenting the picture of bright-red anastomosing channels with brighter interspaces (Fig. 39, Plate III). The choroidal vessels are most markedly visible in the periphery, and are readily distinguished from retinal vessels by being less sharply defined, flat, having no light-streak, by their free anastomosis, and by the fact that they obviously lie in a plane posterior to the latter.

The Region of the Macula Lutea (Fig. 44, Plate V), physiologically the most important part of the fundus, is situated rather less than two disc-diameters to the temporal side of the entrance of the optic nerve, in the line of direct vision. Very often this region presents scarcely any distinctive feature. It is always *devoid of visible vessels*, and is somewhat *darker* than the rest of the fundus. Frequently a *bright spot* is seen in its centre corresponding to the position of the fovea centralis, or there may be two or three of these bright spots. Sometimes the macular region is represented by a bright spot surrounded by an area of dark-red color, about the size of the disc, oval horizontally, and this again encircled by a *bright halo*; this reflex is best seen in the indirect method and is most marked in children of dark complexion, especially if they be hyperopic.

Physiological Variations.—In children of dark complexion the fundus not infrequently presents a bright lustre, which changes its position with movements of the mirror. It is most marked along the blood-vessels; it resembles the

shimmer of *watered silk*. Another peculiar but physiological appearance is sometimes occasioned by *opaque nerve fibres*. In such cases the axis cylinders of some of the optic-nerve fibres regain their medullary sheath at the disc, and continue in this condition for some distance beyond the papilla, presenting one or more whitish areas extending for a variable distance from the disc and terminating in brush-like extremities (Fig. 42, Plate IV).

CHAPTER IV.

AFFECTIONS OF THE EYELIDS.

Anatomy and Physiology.—The eyelids consist of movable folds formed, from before backward, of skin, loose connective tissue, muscular tissue, tarsus and fascia, and conjunctiva (Fig. 45). In addition, they present eyelashes, numerous glands, blood-vessels, lymphatics, and nerves.

The *integument* is thin and delicate, and joined to the subjacent muscles by loose areolar tissue, free from fat. These characteristics explain the readiness with which extravasations of blood and cedematous swellings occur in this region.

The *margin* of each lid presents in front a rounded anterior lip from which the *eyelashes* (cilia) spring; these form two or three rows of short, thick, curved hairs, their roots deeply embedded in the connective tissue and muscle; they are provided with sebaceous follicles, known here as Zeiss' glands. Behind, the lid margin presents a sharp posterior lip; directly in front of this are the openings of the Meibomian glands, and anterior to these, the openings of modified sweat-glands, the glands of Moll. The surface between these two lips is known as the *inter-marginal space*. The margins of the lids unite at an acute angle externally (*external canthus*). At the *internal canthus* the junction presents a rounded space which is occupied by a small, reddish elevation of modified skin, the *caruncle*.

In and behind the subcutaneous connective tissue we find the *muscles* of the eyelids. The *levator palpebræ superioris* is attached to the upper border and anterior surface of the tarsus and to the skin of the middle of the upper lid. The *orbicularis* muscle lies between tarsus and integument, being attached to the latter, but gliding loosely over the former. We also find a layer of *unstripped muscular tissue* inserted into the upper border of the tarsus and known as Mueller's muscle.

The *tarsus* consists of a thin plate of dense fibrous tissue, giving to each lid its firmness; it is larger in the upper than in the lower lid. The tarsi are connected with the lateral walls of the orbit by means of

FIG. 45. — Longitudinal Section of the Upper Lid. S, Skin; O, orbicularis muscle; C, conjunctiva; T, tarsus; M, opening of Meibomian gland; L, lashes.

the internal and external *tarsal ligaments*, and to the upper and lower margins by an aponeurotic layer of fibrous tissue known as the *palpebral fascia* or ligament. In the substance of the tarsus, occurring in parallel rows, are found the *Meibomian glands*, thirty to forty in the upper and twenty to thirty in the lower lid. These are elongated sebaceous glands with blind extremities and numerous cæcal appendages, filled with fatty secretion, and opening on the free margin of the lid.

The *palpebral conjunctiva* is thin, vascular, and closely adherent to the tarsus.

The *arteries* are derived principally from the ophthalmic. The *veins* empty into the ophthalmic, temporal, and facial. The *lymphatics* pass to the pre-auricular, submaxillary, and parotid lymphatic glands. The *third nerve* supplies the levator, the *facial* the orbicularis, and the sympathetic the unstriped muscular tissue (Mueller's muscle). The sensory nerve supply is derived from the *fifth*.

The lids *protect the eyes* from external injury, foreign bodies, undue exposure, and excessive light. They serve to distribute the tears and the secretions from the various glands, thus lubricating the eyeball, keeping the surface of the cornea moist and transparent, and washing away any dust which may have found its way into the eye.

The Common Affections of the Eyelids are blepharitis, hordeolum, chalazion, trichiasis, entropion, ectropion, ptosis, tumors, and injuries.

BLEPHARITIS.

A very common, chronic inflammatory condition of the margin of the lids, associated with the formation of *scales and crusts* (Fig. 48, Plate VI). It occurs under two forms: (1) *non-ulcerative*, (2) *ulcerative*.

Symptoms.—In the *superficial or non-ulcerative form*, the margins of the lids are *swollen and reddened*, and present numerous whitish *scales* at the bases of the lashes. The latter fall out readily, but are replaced, since there is no destruction of the hair follicles.

In the *deep or ulcerative form*, the edges of the lids are *reddened and swollen*, and present yellowish *crusts* which glue the lashes together. On removing these crusts small *ulcers* are seen about the attachments of the lashes; these ulcers bleed readily. The *lashes* become distorted, fall out, and grow scarce, since they are not replaced on account of destruc-

tion of the hair follicles. In both forms there will be itching, soreness, epiphora, and sensitiveness to light.

Sequelæ occur especially in the ulcerative form. There may be permanent *loss of a greater or lesser number of lashes*, hypertrophy of the lid margin, trichiasis, and ectropion.

Etiology.—*Poor hygienic surroundings*; debilitated conditions of the system; following the *exanthemata*, especially measles; exposure to irritating atmosphere—smoke, wind, dust; late hours; insufficient sleep; uncorrected *errors of refraction*, especially hyperopia and astigmatism; chronic *conjunctivitis*; lacrymal disorders; lack of cleanliness. The disease occurs at all ages, but is very common in *children*.

Treatment.—The disease is apt to be obstinate. *Removal of the cause*, if possible, is of the greatest importance. *Cleanliness*, change of faulty habits, and correction of errors of refraction are great aids to local treatment. The edges of the lids must be *cleansed* thoroughly with soap and water, or water to which a little borax or bicarbonate of sodium has been added (applied upon absorbent cotton), using enough friction to *remove all scales and crusts*, dried, and then covered with a two-per-cent. *ointment of the yellow oxide of mercury*, ammoniated mercury, or ichthyol. In the ulcerative form an occasional application of one- or two-per-cent. solution of *silver nitrate* to the raw spots will prove useful. In severe and long-standing cases it will be necessary to *pull out all the lashes*, and then to apply the treatment given above.

HORDEOLUM OR STYE.

A circumscribed, acute inflammation of the *tissues about the follicle of an eyelash*, generally ending in suppuration.

Symptoms.—A red swelling (Fig. 46, Plate VI) appears at the *margin of the lid*, accompanied by pain, tenderness, and often by considerable œdema. Very soon a *yellowish point* will be seen, indicating suppuration.

Etiology.—Styes occur at *all ages*. They are very common in young adults. They often appear in *crops*. They are fre-

quently associated with a *deranged condition* of the system, constipation, and uncorrected *errors of refraction*.

Treatment.—It is sometimes possible to *abort* a sty by the use of cold compresses. As a rule, however, this is unsuccessful. *Hot compresses* are then indicated to hasten suppuration. As soon as a yellow spot is seen, the pus should be *evacuated* either by pulling out one or more lashes or by a horizontal incision. To prevent the formation of others, the *general health* should be looked after and *errors of refraction* corrected. Calcium sulphide, gr. $\frac{1}{8}$ t.i.d., or syrup of the hypophosphites with iron, 3 i. t.i.d., may be of service.

CHALAZION.

Chalazion (*tarsal tumor, tarsal cyst, Meibomian cyst*) is an *enlargement* of one of the *Meibomian glands* in consequence of stoppage of its duct, accompanied by a *chronic inflammation* in the surrounding tarsus. It occurs most frequently in adults. Very often several are found at the same time.

Symptoms.—The process develops slowly with insignificant or no symptoms until, after weeks or months, it has reached the size of a small or large pea. Then it presents a noticeable swelling (Fig. 47, Plate VI), which feels hard, and is adherent to the tarsus, but not to the skin. On everting the lid its situation is shown by *discoloration of the conjunctiva* and sometimes by a small mass of granulation tissue. Sometimes chalazia *disappear* spontaneously; occasionally they *suppurate*, this change being accompanied by inflammatory symptoms. They may be annoying merely on account of the *disfigurement*, or on account of the conjunctival irritation which they occasion.

Treatment.—*When small*, they need not be interfered with. Occasionally we can cause their disappearance by the frequent application of *ointments* of the yellow oxide of mercury, ammoniated mercury, or boric acid, associated with *massage* and *hot compresses*. *When larger*, we remove them by *operation*, usually through the *conjunctiva*: The eye is anæsthetized with holocain or cocaine, the lid everted, and a *vertical incision* is made through conjunctiva and wall of the chalazion with a

FIG. 49.—Ectropion.

FIG. 50.—Chronic Dacryocystitis with Distention of the Lacrimal Sac.

FIG. 51.—Acute Dacryocystitis.

small scalpel (Fig. 52), or Beer's knife (Fig. 53); the contents (Meibomian secretion, granulation tissue, and mucilaginous fluid) are removed and the walls thoroughly *scraped* with the chalazion scoop (Fig. 54). If a drop of a four-per-cent. solution of eucaine B be injected into the cyst, the operation will be practically painless.

When the chalazion is of large size and more accessible externally, or when it suppurates and points externally, it

FIG. 52.—Small Scalpel.

FIG. 53.—Beer's Knife.

FIG. 54.—Chalazion Scoop.

FIG. 55.—Chalazion Forceps.

may be advisable to operate through the *skin* by means of a *horizontal incision*; the tumor may be excised or merely incised and curetted; one or two stitches are then employed. In such cases the chalazion forceps (Fig. 55) is applied with the ring blade surrounding the tumor on the cutaneous surface, the instrument being tightened so as to furnish a bloodless field.

Following the operation the cyst will be filled with a blood clot; this causes a continuation of the disfigurement for several days; absorption may be hastened by gentle massage for a few minutes several times a day.

TRICHIASIS.

Trichiasis is an *inversion* of a varying number of *lashes*, so that they rub against the cornea (Figs. 57 and 62).

Distichiasis is an infrequent condition, usually congenital, in which the lashes can be separated into two rows, the pos-

FIG. 56.

FIG. 57.

FIG. 58.

FIG. 59.

FIG. 60.

FIGS. 56-60.—Section of the Upper Lid, showing Normal and Abnormal Position of Tarsus and Lashes. Fig. 56, Normal lid; Fig. 57, trichiasis; Fig. 58, distichiasis; Fig. 59, entropion; Fig. 60, ectropion.

terior of which is directed backward so as to rub against the eyeball (Fig. 58).

In both of these conditions the *margins of the lids have a normal position*, the displacement affecting the lashes only.

Symptoms.—The misdirected lashes cause *mechanical irritation* and *injury to the cornea*, with irritation, pain, lachrymation, photophobia, opacities, and ulceration.

Etiology.—The most frequent cause is *cicatricial contraction* of the conjunctiva and tarsus in old cases of *trachoma*. Other

FIG. 61.—Cilia Forceps.

causes are blepharitis, burns, injuries to the lids, and operations upon the lids.

Treatment.—1. *Epilation*.—When the misdirected lashes are few in number, we may epilate with the *cilia forceps*

(Fig. 61), repeating this every few weeks, since the lashes grow again.

2. *Electrolysis*.—A sponge electrode corresponding to the positive pole is applied to the temple, and a fine platinum needle forming the negative pole is introduced into the hair follicle, destroying the latter; a very *weak galvanic current* (2 milliamperes) is employed. This method results in a permanent cure, but is quite painful; cocaine should be injected into the lid margin.

3. *Operation*.—When a great number or all of the lashes are misdirected, operations must be performed. These have for their object *correction of the faulty position or transplantation of the lashes*. Since trichiasis is frequently associated with entropion, these operations will be considered in connection with the latter disease.

ENTROPION.

A rolling in of the margin of the lid (and with it the lashes) (Figs. 59 and 62).

Varieties.—There are two forms: (1) *Cicatricial*, due to cicatricial changes in the conjunctiva and tarsus, most commonly affecting the *upper lid*. (2) *Spasmodic*, due to spasm of the palpebral portion of the orbicularis muscle, almost always occurring in the *lower lid*. The second variety is generally found in old persons (*senile entropion*) who are predisposed through relaxation of the palpebral skin and the deep position of the eyeball resulting from the absence of fat.

FIG. 62.—Entropion of the Lower Lid. Trichiasis of the Upper Lid.

Symptoms.—Those due to *mechanical irritation and injury to the cornea*: irritation, pain, lacrymation, photophobia, opacities and ulceration of the cornea.

Etiology.—*Cicatricial form*: principal cause, the cicatricial

changes in old cases of *trachoma*, also burns and other injuries to the lids, and operations upon the lids. *Spasmodic form*: atrophy or absence of eyeball, blepharospasm, inflammatory conditions of the lids and conjunctiva, and the prolonged wearing of a bandage (in senile patients).

Treatment.—*Non-operative* treatment may be of service in the *spasmodic variety*. If a bandage causes the entropion, we must either leave this off or apply a small roll of lint to the orbital margin beneath the bandage, exerting pressure in such a manner as to *neutralize the inversion*. In other cases we try to *remove the cause*. The lid may be kept everted for a few days by *collodion* painted on the external surface, or by *adhesive plaster* passing from the margin of the lid to the cheek. If these simple means do not answer, an *operation* is indicated. In the *cicatricial form*, operation is always necessary.

Operations for Trichiasis and Entropion.—The choice of an operation (there are a great many) is influenced

FIG. 63.—Horn Plate.

FIG. 64.—Knapp's Entropion Forceps.

by the peculiarities existing in the individual case. The object of these operations is to remove the displaced lashes from contact with the eyeball either (1) by *changing the direction of the lashes* from a faulty to a correct one, (2) by *transplanting* the offending zone, or (3) by *straightening the curved tarsus*.

In these operations we use either a horn plate (Fig. 63), or the entropion forceps (Fig. 64), to protect the eyeball, check

hemorrhage, and give proper support to the lid. The horn plate is passed beneath the lid and pressed forward. If the lid clamp be used, its solid blade is passed beneath the lid, and the latter secured by tightening the screw of the instrument.

The Jaesche-Arlt Operation attaches the zone of hair follicles at a higher level by *shortening the skin of the lid*. The lid is split through its entire length in the intermarginal space,

FIG. 65.—The Jaesche-Arlt Operation for Entropion. Incisions.

FIG. 66.—The Jaesche-Arlt Operation for Entropion. Completed.

so that the anterior lip contains the hair follicles. A second incision, dividing the skin down to the tarsus, is made 4 mm. from and parallel to the margin of the lid. A third incision extends upward in a curve between the two ends of the second incision. The elliptical piece of skin bounded by the second and third incisions is dissected away (Fig. 65) without injury to the orbicularis and the margins of the defect are united by fine silk sutures (Fig. 66). In this manner the strip of integument containing the cilia is drawn upward and the lashes are tilted forward, away from the cornea. The area from which the skin and lashes have been displaced may be allowed to cicatrize, or may be covered by the excised strip of integument properly trimmed, which will attach itself in a few days.

Hotz's Operation raises the zone of hair follicles by *attaching the skin to the upper border of the tarsus*. A curved incision is made through the skin of the lid following the

upper border of the tarsus, from 2 mm. above one canthus to a corresponding distance above the other. While the edges of the wound are separated, a narrow strip of orbicularis along the upper border of the tarsus is excised. The sutures, three or more in number, are then passed through the lower wound margin, upper border of tarsus, returning through the orbito-tarsal fascia, and finally through the upper wound mar-

FIG. 67.—The Hotz Operation for Entropion.

FIG. 68.—The Hotz Operation for Entropion (Shown in Section).

gin (Figs. 67 and 68). This operation may be modified by the addition of an intermarginal incision, by grooving the tarsus, and by excising a horizontal strip of integument.

The Streetfeild-Snellen Operation aims at straightening the inverted lid by the *removal of a wedge-shaped piece from the tarsus*. A transverse incision is made through the skin, 2 mm. above and parallel to the margin of the lid along its entire length. A strip of orbicularis is excised, thus exposing the tarsus. A wedge-shaped piece, the apex of which is directed toward the conjunctiva, is removed from the tarsus along its entire length. The cut surfaces of the tarsus are brought into contact by three sutures, provided with needles at both ends, in the following manner: One needle is passed through the tarsus above the groove; both needles are then

carried down in front of the wound in the tarsus, and then between tarsus and skin, and brought out just above the free margin of the lid (Fig. 70) about 4 mm. apart. The two

FIG. 69.—The Streatfeild-Snellen Operation for Entropion. One of the Threads has been Tied.

FIG. 70.—The Streatfeild-Snellen Operation for Entropion (Shown in Section).

threads are tied upon a bead (Fig. 69) and then turned up over the forehead and secured by plaster. The cutaneous wound closes of itself. More pronounced eversion is produced if the threads are passed behind the cilia, emerging just above the posterior lip of the lid margin (Herbert's modification).

Operations for Spastic (Senile) Entropion include (1) *excision of a horizontal strip of skin* with the underlying orbicularis, the width being gauged so that when pinched up it shall cause the disappearance of entropion without producing ectropion; the margins of the wound are then united by silk sutures; (2) *subcutaneous sutures* (Gaillard-Arlt), which enter through the skin near the lid-margin and emerge three-quarters of an inch below (Fig. 71); parallel threads are

FIG. 71.—Gaillard-Arlt Sutures for Entropion. Threads in Place.

FIG. 72.—Gaillard-Arlt Sutures for Entropion. Threads Tied.

used, forming a loop near the border of the lid; the threads are tightened over a small roll of plaster (Fig. 72); they are allowed to remain in place for a week; in this manner cicatricial bands are formed; this procedure is no longer employed to any great extent except for temporary effect, since with modern surgical methods there is no suppuration and consequently little or no cicatrization upon which the results depend; (3) *Holtz's operation*; and (4) *canthoplasty*.

Canthoplasty consists in an enlargement of the palpebral fissure by division of the external canthus. The lids being separated and stretched at the external canthus with the fin-

FIG. 73.—Canthoplasty.

gers, one blade of blunt-pointed, straight scissors is introduced behind the external commissure as far as possible, and the entire thickness divided, the wound in the skin being made a little longer than that in the conjunctiva. This leaves a rhomboidal wound. The conjunctiva at the apex of the wound is loosened from underlying tissue and stitched to the centre of the incision in the skin. A second suture is passed through the

upper, and a third through the lower part of the wound, uniting conjunctiva to skin (Fig. 73).

The sutures are inserted so as to prevent reunion, thus making the effect *permanent*. If a *temporary* enlargement is desired, we omit the sutures; the operation is then known as *canthotomy* or *temporary canthoplasty*.

The indications are *blepharospasm* associated with spastic entropion, and certain cases of *trachomatous pannus*. *Temporary canthoplasty* is indicated in acute *purulent conjunctivitis* when swelling of the lids exerts injurious pressure upon

the eyeball, in *blepharospasm*, and in the removal of an enlarged eyeball or an orbital tumor.

ECTROPION.

An *eversion of the lid* with exposure of more or less conjunctival surface (Fig. 49, Plate VI, and Fig. 60). It may affect the upper or the lower lid, or both.

Symptoms.—*Epiphora* (from eversion of punctum) causing *excoriations* and *eczema* of the lower lid, which, in turn, through contraction, increase the deformity. The *exposed conjunctiva* becomes reddened and hypertrophied. In marked cases the *cornea* may suffer, as a result of imperfect closure of the lids.

Etiology.—(1) Cicatricial contraction from wounds, operations, burns, ulcers, and caries of the orbital margin or surrounding surfaces (*cicatricial ectropion*). (2) *Chronic conjunctivitis* and *blepharitis* associated with considerable hypertrophy. (3) Relaxation of the skin and orbicularis in old people (*senile ectropion*), affecting only the *lower* lid. (4) Affections of the facial nerve, causing paralysis of the orbicularis (*paralytic ectropion*), affecting only the *lower* lid. (5) Spasmodic contraction of the marginal portion of the orbicularis (*spasmodic ectropion*), seen especially in children with acute conjunctivitis associated with considerable blepharospasm.

Treatment.—*Non-operative*: The *spasmodic form* is frequently relieved by a suitable retaining *bandage* applied after the lid has been properly placed. In the *paralytic form* we employ a bandage, at the same time attempting to cure the facial paralysis. In the *senile form* we put on a bandage at night, and slit open the lower canaliculus; we instruct the patient, when wiping away the tears, to press upward and inward and not downward and outward. In slight cases of ectropion associated with much conjunctival hypertrophy, painting the exposed surface with two-per-cent. solution of *silver nitrate* may be of service. Careful *massage* of a cicatrix may give some relief. When these simple procedures do not

answer, and in *cicatricial ectropion*, we must resort to *operative intervention*.

Operations for Ectropion.—In *senile and paralytic* forms of ectropion the lid may be replaced by (1) Snellen's sutures; (2) by reduction of the length of the lid-border; and (3) by tarsorrhaphy.

Snellen's Sutures.—Two loops of thread are placed at the junction of the middle with the outer and inner third of the

FIG. 74.—Snellen's Sutures for Ectropion. Threads in Position.

FIG. 75.—Snellen's Sutures for Ectropion. Threads Tied.

lid respectively, entering the everted conjunctiva at its most prominent part (Fig. 74), brought out on the face 2 cm. below and tied over a piece of rubber tubing, so as to produce a slight amount of entropion (Fig. 75); the threads are tightened from day to day until they have nearly cut through, when they are removed. The success of this operation depending upon the contraction

of cicatricial bands caused by suppuration in the track of the sutures, modern surgical conditions have rendered the effects less satisfactory.

Shortening the Margin of the Lid (*Adam's Operation*) is applicable when there is considerable elongation. A wedge-shaped piece is excised from the whole thickness of the lid (Fig. 76), the base corresponding to the margin of the lid and varying from 5 to 10 mm. in width, according to the amount of shortening required; the edges are brought together by a harelip pin and the cutaneous margins by silk sutures (Fig. 77). The piece may be excised from the centre of the lid; but, to prevent notching, it is better to operate at the external canthus.

For *cicatricial ectropion* a great many operative procedures have been advocated. An essential condition for success is the *thorough division of all cicatricial adhesions*, so that the lid assumes a natural position, the object of any operation being

to prevent recicatrization. If the ectropion is slight and but little skin has been lost, it may be sufficient to *divide the cicatricial bands subcutaneously*, or to cut out the scar portion

FIG. 76.—Adam's Operation for Ectropion.
Incisions.

FIG. 77. - Adam's Operation for Ectropion.
Completed.

and bring the margins of the wound together by sutures. A procedure very frequently used is

The V Y Operation (*Wharton Jones*).—A V-shaped incision is made with the apex directed away from the palpebral margin, the incision including the cicatrix (Fig. 78). The skin

FIG. 78.—The V Y Operation for Ectropion.
The incisions have been made and the
Sutures are in position.

FIG. 79.—The V Y Operation for Ectropion.
Completed.

is freed from underlying parts, not only in the V-shaped area, but also to either side. The V-shaped area is slid upward until slight inversion of the lid margin is produced. The

margins of the incisions are then brought together by sutures in such a manner that the figure Y results (Fig. 79).

In more *extensive cicatricial ectropion* a *plastic operation* is usually required (blepharoplasty).

Blepharoplasty consists in *covering the defect* formed by the excision of a cicatrix, new growth, or extensive ulceration, with *skin flaps with a pedicle*, taken from some adjacent part, or by means of *skin grafts*. In such operations it is customary to close the lids temporarily by several sutures so as to prevent the contraction of the cicatricial tissue from undoing the result accomplished by the operation. Of the innumerable blepharoplastic operations with pedunculate skin-flaps, Knapp's, Dieffenbach's, and Fricke's methods are the ones most commonly employed.

Knapp's Method (lower lid) consists in detaching a *lateral flap* on each side of the defect in the lid, freeing it from adjacent tissue, drawing the two flaps over the defect, and uniting them by a vertical row of sutures.

Dieffenbach's Method (lower lid) makes use of an *adjacent quadrangular flap* taken from the cheek and slid inward so as to cover the defect of the lid.

Fricke's Method (upper or lower lid) consists in taking a *tongue-shaped flap* somewhat larger than and having the shape of the defect in the lid *from the temple or cheek*; the base of the flap adjoins one end of the lid wound, and is the part which becomes twisted when the flap is transplanted into the defect.

Skin-Grafting.—The defect is filled in by *one large piece* of skin or by a *number of smaller ones*, after the lid has been fastened in its proper position by temporarily suturing the two lids together. The grafts are taken from some part of the body in which the skin is *thin and delicate*, such as the inner side of the arm or thigh. The area of the graft, or grafts, must be *one-third larger* than the defect to be covered, to allow for shrinkage. The graft may consist of the *entire thickness of the skin* (Wolfe's method), or comprise only the *epidermis* (Thiersch's). The area to be covered must be clean and free from blood. When in place, the graft is covered

with a layer of rubber or silk protective, and then with an antiseptic dressing. The dressing is not disturbed for three days, and the original protective layer over the graft is often left in place still longer.

Skin-grafting is now used very extensively and with very good results. If a portion of the graft sloughs, the corresponding defect can be freshened and another graft applied. This method causes less disfigurement than when pedunculate flaps are used. *Thiersch's grafts*, being thinner and softer than Wolfe's, produce better results cosmetically, and the lid is not so heavy.

Tarsorrhaphy.—The object of this operation is to *reduce the width of the palpebral fissure* by uniting the edges of the lids at the *outer commissure*. The edges of the lids are approximated at the outer canthus to the required extent, so as to give the operator exact knowledge as to how much union is desired. A horn spatula is passed behind the outer commissure, and the desired length of the border of each lid is excised, including the hair follicles. The length of the flap varies according to the effect desired (about 3 to 6 mm.); its breadth is about 1 mm. To obtain firmer adhesion, the border of the lid, excluding the cilia, is denuded for 2 or 3 mm. beyond the point at which the first incision stops. The denuded edges are then brought together by silk sutures (Fig. 80). This operation is indicated in lagophthalmos, especially in Basedow's disease, in some cases of senile and paralytic ectropion, and in connection with blepharoplasty.

FIG. 80. —Tarsorrhaphy.

PTOSIS.

A drooping of the upper lid due to paralysis or deficient development of the levator. All degrees of ptosis occur. When marked, it interferes with vision by covering the pupil.

Patients attempt to raise the lid by forced action of the occipito-frontalis muscle, wrinkling the skin of the forehead (Fig. 81); when the condition is bilateral, they favor exposure of the pupil by throwing the head backward; this attitude is characteristic.

Etiology.—Ptosis may be congenital or acquired. When *congenital*, it is usually *bilateral*, due to *deficient development*

FIG. 81.—Ptosis (Right Side).

of the levator, and often associated with other congenital defects. *Acquired* ptosis is usually *unilateral*; it is caused by *paralysis* of the branch of the *third nerve* which supplies the levator, and is usually associated with paralysis of other ocular muscles supplied by the oculomotorius. When not associated in this way, it is not infrequently the result of *cerebral disease*.

Mechanical ptosis is a variety due to (1) increased weight of the lid (trachoma, tumors, etc.); (2) lack of support (atrophy of globe and after enucleation); and (3) lack of connective-tissue connection between skin and levator and upper border of orbit, in which the relaxed skin forms a fold which falls over the margin of the lid.

Treatment.—In the ordinary variety of the acquired form we *seek the cause of the paralysis* of the third nerve and treat this; *syphilitic cases* respond well to treatment. *Electricity* is used. If this treatment fails to remedy the deformity after a lengthy trial, in the congenital variety and in some mechanical cases, *operation* is indicated.

Operations for Ptosis.—Operations for ptosis rarely give perfectly satisfactory results. Their aim is either (1)

to produce a *shortening of the skin* of the upper lid with or without excision of a strip of orbicularis; (2) an *elevation of the lid* by connecting it directly with the fibres of the occipitofrontalis muscle; or (3) an *advancement*, resection, or both, of the *levator muscle*.

Excision of an Elliptical Strip of Skin is a very common and simple method of operating; the effect is limited, and consequently the procedure is adapted for *slight cases* only. A fold of integument (just enough to produce the desired effect) is grasped by forceps and cut off with the subcutaneous tissue by means of scissors; the edges of the wound are sutured.

Excision of a Strip of Orbicularis (*Graefe's Operation*).—A horizontal incision of the skin is made across the entire lid, 5 mm. above its margin. The edges of the wound are separated and undermined and a band of orbicularis is excised. If the skin be redundant, a strip may be excised. The wound is closed by deep sutures, which include muscle and skin.

Pagenstecher's Sutures attempt to bring the occipitofrontalis to act on the lid by means of cicatricial bands. A silk thread is provided with a needle at each end. One of these needles enters the skin just above the lid margin, and after passing horizontally a short distance, passes upward beneath the skin and emerges above the eyebrow. The other needle enters the first puncture, and passing upward, emerges by the side of the first. The result is a subcutaneous loop of thread just above the lid margin. The two ends of the thread are tied over a piece of rubber tubing. The threads are allowed to remain until suppuration occurs in their tracks, and then removed, or allowed to remain and gradually drawn out above. Two or three such double sutures are used.

Panas' Operation (as modified by Allport).—A horizontal incision (3 cm.) is made in the eyebrow down to the periosteum, and another (2 cm.) equally deep, at the margin of the orbit; this bridge of skin and muscle is undermined. A tongue-shaped flap (15 mm. wide) is marked out, its surface denuded of epithelium, and separated from the lid, including muscle. The free end of this flap corresponds to the lower border of the bridge of tissue at the orbital margin and its

base to the upper margin of the tarsus; here a short, horizontal incision is made through the skin toward the inner and outer canthi respectively (Fig. 82). This flap is drawn up under the bridge and stitched to the upper edge of the upper wound by three sutures. To avoid ectropion, an additional suture, which passes through the tarso-orbital fascia and con-

FIG. 82.—Panas' Operation (Allport's Modification). The Incisions have been made and the Sutures are in place.

FIG. 83.—Panas' Operation (Allport's Modification). Completed.

junctiva only, is applied at each side. The square-shaped lateral flaps are trimmed by cutting off their corners and are sutured to adjacent parts (Fig. 83). The sutures are removed after four days.

Epicanthus is a congenital condition, usually bilateral, in which a perpendicular fold of the skin extends from the root of the nose to the inner end of the brow, concealing the inner canthus and caruncle. In Mongolians it is a racial characteristic. In slight degree it is often seen in young children associated with a flattened bridge of the nose, and often disappears with the development of the face. When sufficiently marked to constitute a deformity, it can be relieved by excising an elliptical piece of skin from the root of the nose, long axis vertical, and stitching together the free margins.

Herpes Zoster Ophthalmicus is characterized by a unilat-

eral, *herpetic eruption* following the distribution of the ophthalmic division of the *fifth nerve*. The affection begins with severe neuralgic *pain* of one side of the head and face, and constitutional disturbance. The eruption presents *vesicles* situated upon inflamed bases; the vesicles are at first filled with clear fluid, but this soon becomes cloudy; subsequently discolored crusts form and drop off, leaving permanent and disfiguring *scars*. In some cases the nasal branch is also attacked and then the eyeball becomes implicated; the cornea presents one or more vesicles changing to ulcers; and the iris and ciliary body and even the entire globe (panophthalmitis) may be involved.

The affection is due to disease of the Gasserian ganglion. It is most frequently observed in *elderly* patients of feeble constitution. Its *duration* is from several weeks to several months. The *prognosis* is usually good, but is serious when the cornea is involved.

Treatment.—Bland dusting powders (bismuth subcarbonate or talcum to which a small proportion of cocaine has been added), or ten-per-cent. ichthyol ointment; the galvanic current may be of service. Internally, quinine and iron, and the salicylates are most useful. The severe pain must often be controlled by opium or morphine.

TUMORS OF THE LIDS.

Benign Tumors include xanthelasma, molluscum, verruca (wart), fibroma, cyst, nævus, and milium.

Xanthelasma is a flat or slightly raised, yellowish discoloration beneath the skin found most frequently near the inner canthus in elderly women. It is due to degeneration of the muscle fibres.

Molluscum is a small, white, rounded tumor, about the size of a small pea, presenting a depression at its apex; several usually occur at the same time. They are considered contagious by some authorities. They represent a diseased condition of the sebaceous glands.

Milium is a small, yellowish-white elevation about the size of a pin's head, due to retention in a sebaceous gland.

The others resemble tumors of the same class occurring in other parts of the body. Benign tumors of the lids may be *excised*, providing too great a loss of skin is not occasioned by the operation.

Malignant Tumors.—Sarcoma is rare.

Carcinoma, when it attacks the lids, usually assumes that form of *epithelioma* known as *rodent ulcer*. This occurs in *elderly* persons, especially at the *inner end of the lower lid margin*. It begins as a small pimple or wart, covered by a crust, soon changes to an *ulcer with indurated walls*, and spreads, if unchecked, to neighboring parts. Its growth is, however, *slow*, and many years may elapse before it assumes any considerable size. *Treatment* consists in *excision*; this is always possible if done early. If advanced, we may excise the lesion and cover the defect by blepharoplasty. If all the diseased tissue cannot be excised, *escharotics* (chloride of zinc paste or glacial acetic acid), the *electro-cautery*, the *x-rays*, or radium, may be used.

INJURIES OF THE EYELIDS.

These are quite common, and include contusions, wounds, burns, and insect bites. Ecchymosis and oedema are often marked symptoms on account of the looseness of the subcutaneous connective tissue.

Ecchymosis (*"black eye"*) is usually of no importance, merely causing disfigurement, which lasts one or two weeks. If seen immediately, *cold compresses* may be of service. After a day or two, *hot compresses* and gentle *massage* are indicated to promote absorption of the extravasated blood. Occasionally in debilitated individuals, especially if associated with abrasion, abscess of the lid results, and may require horizontal incision. In fracture of the base of the skull, blood may travel along the floor of the orbit, and after a day or two appear in the lower lid and bulbar conjunctiva.

Insect-bites give rise to a great deal of *swelling*, which is best controlled by *cold compresses*.

Incised Wounds cause considerable gaping, if vertical, on account of division of the orbicularis, and then the scar is apt

to be noticeable; if horizontal, the lips of the wound do not tend to separate, and usually heal without deformity. Incised wounds should be *cleansed* and *stitched* at once, using *fine silk* and *delicate needles*. A vertical wound of the margin must be carefully sewed so that no indentation will remain.

Lacerated and Contused Wounds, if extensive and accompanied by much swelling, should not be closed at once. The wound should be thoroughly *cleansed*, and after the swelling has subsided the edges may be *brought together*. Injured parts, however slenderly attached, should not be removed. Care must be taken not to produce *deformity* or shortening by too tight sutures. It may be advisable to use *skin-grafts*.

Burns should be irrigated with solution of boric acid, dried, and covered with a *bland oil* or *ointment*. When granulating, *skin-grafts* should be supplied if the defect is extensive.

Emphysema associated with injury to the lids denotes a solution of continuity of the walls of the orbit, permitting communication with the *neighboring air cavities*. The lids will present a *soft swelling* of considerable size, often closing the palpebral aperture; bubbles of air, becoming displaced in palpation, give rise to the sensation of *crepitation*. A *firm bandage* will hasten the disappearance of the air. The patient must be instructed to *avoid any straining efforts* such as blowing the nose, which will increase the emphysema.

CHAPTER V.

DISEASES OF THE LACRYMAL APPARATUS.

Anatomy and Physiology.—The lacrymal apparatus consists of a *secretory portion*, the lacrymal gland, and an *excretory portion*, which collects the tears and conducts them into the inferior meatus of the nose.

The *lacrymal gland* is a small, oblong body, placed in the upper and outer part of the orbit and divided into two portions. The upper part, the larger, about the size of a small almond, is situated in a depression in the orbital plate of the frontal bone, the lacrymal fossa, to which it is fixed by connective tissue; the lower division, the smaller, is known as the accessory lacrymal gland, and is placed just beneath the outer part of the conjunctiva of the fornix. In structure the lacrymal resembles the salivary glands, consisting of acini containing cuboidal cells. The excretory ducts of both portions of the gland, the lacrymal ducts, six to twelve in number, pass downward and empty into the external half of the superior fornix conjunctivæ by separate orifices.

FIG. 84.—The Excretory Portion of the Lacrymal Apparatus.

The *excretory portion of the lacrymal apparatus* (Fig. 84) consists of the puncta, the canaliculi, the sac, and the duct. The *puncta* are two minute openings, one of which is seen upon an elevation on each lid about 6 mm. from the inner canthus; they are the orifices of the *canaliculi*.

The latter extend vertically for a short distance, and then, continuing at right angles, pass horizontally inward in a curved course, and empty separately or together into the lacrymal sac.

The *lacrymal sac*, situated at the inner side of the internal canthus, is the upper, dilated portion of the lacrymo-nasal duct, and is placed in a groove formed by the lacrymal bone and the nasal process of the superior maxillary bone; it measures 12 mm. in the vertical and 6 mm. in the horizontal and transverse diameters; its walls are thin; it is covered in front by the internal tarsal ligament and some fibres of the orbicularis muscle.

The *nasal duct* passes downward and slightly outward and backward in a canal formed by the superior maxillary, lacrymal, and inferior turbinated bones, and terminates below in the fore part of the infe-

rior meatus of the nose; its length varies from 18 to 24 mm., and its diameter from 4 to 6 mm.; it is somewhat contracted where it joins the sac and again at its lower extremity. Both sac and duct are formed of fibrous and elastic tissues, and mucous membrane lined with columnar epithelium which may be ciliated; the lower part of the duct is surrounded by a dense plexus of veins.

The *lacrymal secretion* is a slightly alkaline liquid containing a comparatively large amount of sodium chloride. Ordinarily the lacrymal gland secretes just enough to moisten the eyeball, and this is lost by evaporation. As the result of psychical stimulation or of irritation of the eye or the nose, there is increased secretion. The conveyance of tears from the conjunctiva to the lacrymal sac is effected by the act of winking, the lubrication of the margins of the lids by fatty material ordinarily preventing the tears from flowing over.

Epiphora ("watery eye"), an *overflow of tears* upon the cheeks, is a very pronounced symptom in all affections of the tear-conducting apparatus. It may also be dependent upon increased secretion (foreign bodies, inflammations, exposure to bright light and smoke, affections of the nose, irritation affecting the terminal twigs of the trigeminus). The two forms may be combined.

Anomalies of Puncta and Canaliculi.—Normally, the lower punctum is directed backward and upward toward the eyeball.

Eversion of the Punctum.—In this anomaly the lower punctum looks forward and away from the depression in which the tears accumulate, and the result is *epiphora*. The condition may be due to a relaxed state of the lids in *old age*, to *conjunctivitis*, *blepharitis*, and *ectropion*. It is remedied by *splitting open* the lower canaliculus with Weber's probe-pointed knife (Fig. 85), and *keeping it open* by separating the edges of the incision daily for two or three days.

FIG. 85.

FIG. 86.

FIG. 87.

FIG. 85.—Weber's Probe-Pointed Canaliculus Knife.

FIG. 86.—Canaliculus Dilator.

FIG. 87.—Stilling's Lacrymal Knife.

Contraction and Obliteration of the Puncta and Canaliculi may be congenital, or acquired as a result of wounds and chronic inflammations of this region. Foreign bodies (eyelash or concretion) may obstruct the canaliculi. Treatment consists in removing foreign bodies with a delicate forceps, if possible. In the other cases *dilatation* with a fine conical sound (Fig. 86), or *splitting open* the canaliculus is indicated.

Diseases of the Lacrymal Apparatus may be divided into those of the gland and those of the conducting portion.

The former (acute and chronic *dacryoadenitis*) are *very rare*; the latter (acute and chronic *dacryocystitis*) are *very common*.

CHRONIC DACRYOCYSTITIS.

A *chronic inflammation of the lacrymal sac* usually due to an *obstruction in the nasal duct*. It is also known as *blennorrhœa* or *catarrh of the lacrymal sac*, and as *mucocoele* (Fig. 50, Plate VI).

Symptoms.—The constant symptom is *epiphora*, increased by exposure to cold, wind, dust, smoke, etc. There may be *fulness* in the region of the lacrymal sac. By pressing upon the distended sac, a *viscid fluid* of whitish, yellowish, or greenish color (depending upon the amount of pus) escapes from the puncta; but sometimes the sac is emptied in the reverse direction, and the accumulation is pressed into the nose.

Course is chronic and extends over *years*; a long period may elapse before the patient seeks relief. After the muco-purulent material has filled the sac for a long time, there is *atrophy* of its mucous membrane and *distention* of its walls. A form of chronic conjunctivitis affecting chiefly the inner canthus (*lacrymal conjunctivitis*) and blepharitis are frequently present; eczema occurs sometimes, and there may be more or less ectropion. As a result of contamination by micro-organisms from the conjunctiva (especially streptococci, Fig. 108, Plate VIII), a *purulent inflammation* of the lining of the sac is set up.

The *infectious character* of the accumulation is shown, when

any abrasion or ulcer of the cornea exists, by the readiness with which the wound or ulcer becomes infected. In operations upon the eye, such a condition is a very frequent cause of infection.

Etiology.—In most cases there is *stricture of the nasal duct*, the result of an affection of the nasal cavity, usually *rhinitis*. The duct is predisposed to obstruction by the existence of a plexus of veins encircling its lower end. As a result of rhinitis, there is swelling or cicatricial contraction of the mucous membrane of the duct. More rarely, pressure from tumors (polyps and hypertrophies), ulcerations, caries, and periostitis are responsible.

Treatment.—In recent and slight cases, we may relieve the epiphora by curing the nasal affection which produces the obstruction. Locally, *stimulating and astringent remedies*, such as zinc sulphate and the ointment of the yellow oxide of mer-

FIG. 88.—Anel's Lacrymal Syringe.

cury, may be applied to the inner part of the eyeball, followed by gentle *massage* over the sac so as to favor entrance of some of the remedy. The patient is instructed to empty the sac by pressure several times a day. The sac should be washed out with *warm and weak solutions* of salt, *boric acid*, or zinc sulphate, using a small syringe with delicate nozzle (Fig. 88). If the contents of the sac are mucopurulent or purulent, semi-weekly injections of a five-per-cent. solution of *argyrol* will be of value. It is often necessary to dilate the lower punctum

with the fine conical sound (Fig. 86) before the nozzle can be introduced. If the nasal duct is pervious, the solutions will enter the nose and escape from the anterior nares when the patient inclines the head forward.

If the mild treatment just mentioned is unsuccessful, we resort to *dilatation with probes*—either Weber's conical sound

FIG. 89.—Weber's Conical Sound.

FIG. 90.—One of Bowman's Lacrymal Probes.

(Fig. 89), or Bowman's probes (Fig. 90) which are numbered from 1 to 8, the largest (8) being about 2 mm. in thickness; they are curved before use. Probes of greater calibre (Theobald's) are sometimes used. Though the smallest probes may be passed through the natural opening, it is customary to *slit open the lower canaliculus* preliminary to probing the duct.

To Slit Open the Canaliculus.—The surgeon usually stands behind and supports the patient's head against his body. Weber's probe-pointed canaliculus knife (Fig. 85) is most

FIG. 91.—Slitting Open the Lower Canaliculus. First Step.

FIG. 92.—Slitting Open the Lower Canaliculus. Final Step.

frequently used. The lower lid is pulled outward by the thumb of one hand, and with the other the knife is introduced vertically, until it passes the punctum, and then horizontally;

its edge is upward and looks toward the eyeball so as to cut into the conjunctiva and not into the integument (Fig. 91). It is pushed horizontally inward until its extremity meets with the firm resistance of the inner bony wall of the sac; then the knife is raised into a vertical position (Fig. 92).

To Pass Probes into the Nasal Duct.—Commencing with a small size, say a No. 3, we pass this horizontally inward exactly as the knife is passed, the surgeon standing behind (or in front of) the patient. When the probe reaches the inner wall of the sac, which we can be certain of when in lifting the probe there is no wrinkling of the skin of the lower lid, it is raised so that its lower end points toward the furrow between nose and cheek. It is then pushed downward gently, until it

FIG. 93.—Passing a Probe into the Nasal Duct.

reaches the floor of the nasal fossa (Fig. 93). If the probe does not pass readily, we must not use force, but withdraw it slightly and try again, or try a smaller or larger size. The probe is left in from fifteen to thirty minutes, and the proceeding is repeated every other day, gradually using larger probes; then the intervals between probing are increased.

Sometimes the *stricture is cut*, a strong, narrow knife (Fig. 87) being passed in the same manner as a probe, and the obstruction divided in two or three directions; this is immediately followed by probing.

In some cases leaden or silver *styles* are passed and left in for days or weeks.

Even with all this treatment, permanent cures are rather

the exception; there will be *temporary relief* and then the affection returns. The most favorable cases are those in which there is merely swelling of some part of the duct and the condition has not existed for too long a period. When *complete occlusion* exists, we cannot expect a cure. In such cases and in others of an *obstinate* nature, we may *slit open both the upper and lower canaliculi* and divide the tissue between these two, keeping open the cavity thus formed until there is no longer any tendency to unite. This converts the sac into an open space which the patient can keep clean.

In obstinate and long-standing cases in which other measures have failed, particularly if the sac is dilated or a lacrymal fistula is present, *radical treatment* is indicated. In such instances operation is advisable in order to relieve the discomfort of epiphora, to remove the liability to repeated attacks of abscess, and to get rid of an ever-present infectious collection which, when the cornea is affected, becomes a source of danger to the eye. Such radical relief may be obtained through (1) *incision* and treatment of the walls of the sac, (2) *destruction* of the sac, and (3) *extirpation* of the sac.

Incision into the Lacrymal Sac and Direct Treatment of its Walls.—The sac is exposed by an incision over its anterior surface, this step being facilitated by the passage of a probe through the divided canaliculus. After the rather profuse hemorrhage ceases, the lining of the sac is scraped with a sharp curette or brushed with a five-per-cent. solution of nitrate of silver or touched with the solid stick of nitrate of silver throughout its entire extent. The sac and wound are then filled with a packing of sublimate or iodoform gauze which is renewed daily. If in a few days the mucous lining of the sac appears healthy and free from purulent secretion, we allow the external wound to close.

Destruction of the Lacrymal Sac.—The sac is cut into and its cavity thoroughly exposed. Then its mucous lining is destroyed by galvano-cantery, chloride-of-zinc paste, or solid stick of nitrate of silver; the sac and wound are packed with sublimate or iodoform gauze and kept open until the cauterized

area has been cast off; it may be necessary to repeat the cauterization.

Extirpation of the Lacrymal Sac.—A general anæsthetic is usually necessary, but the operation may be performed under local anæsthesia. A curved incision, commencing above just below the internal canthal ligament and passing downward and outward along the orbital margin for 2 to 3 cm., divides the skin and underlying fascia until the sac is exposed (Fig. 94). Hemorrhage is annoying, but can be controlled by retractors (special instruments, Mueller's and Axenfeld's, have been devised), by compression, and by the use of adrenalin solution. The sac is separated with the aid of the handle of a scalpel and blunt scissors, care being taken not to penetrate the wall; its upper extremity is freed; it is cut off as low down in the canal as possible. The canal is curetted; diseased bone which may be present is scraped away. After thorough disinfection, the edges of the incision are brought together with three sutures, dusted with iodoform, and a dressing applied by means of which constant pressure is exerted; this is kept on for a few days. There is usually primary union with obliteration of the cavity, and the scar is scarcely visible.

FIG. 94.—Extirpation of the Lacrymal Sac.

Extirpation is the best of these radical measures. Serious complications are rare. Conduction of the tears is prevented, but there is generally little annoyance from epiphora, probably through cure of the lacrymal conjunctivitis.

ACUTE DACRYOCYSTITIS.

An acute inflammation of the region of the lacrymal sac occurring in the course of a chronic dacrocystitis, as a result

of an acute exacerbation. It is also known as *Abscess of the Lacrymal Sac* (Fig. 51, Plate VI).

Symptoms.—The skin over the lacrymal sac becomes *red-den*ed and *swollen*; this condition extends to the *lids and conjunctiva*, and is often sufficiently pronounced to lead to a suspicion of erysipelas. There are great *pain* and *tenderness*, some *fever* and constitutional disturbance. After two or three days a yellow discoloration appears at one point; here *pus* will be present, and should be evacuated; this will be followed by relief and a subsidence of symptoms.

The *opening* may *heal* completely, and the case again have the symptoms and slow course of chronic dacryocystitis. In other cases the opening *persists* and the escaping fluid changes its character and becomes watery; this constitutes *lacrymal fistula*. As long as this remains open, the patient is safe; as soon as it closes, he is liable to have a recurrence of abscess. Sometimes merely a minute passage is left, insufficient to admit a probe, from which a drop of fluid escapes from time to time.

Etiology.—Lacrymal abscess involves not only the sac, but the surrounding connective tissue as well. The decomposed contents of the sac find a small defect in the lining, through which *micro-organisms* (especially streptococci) reach the neighboring tissues and excite inflammation and suppuration.

Treatment.—*If the case is seen early*, we try to prevent the formation of abscess, by *pressing out* the accumulation and *syringing* with mild antiseptic solutions (boric acid four per cent., or bichloride 1:10,000). If this cannot be done or is not effective, as is often the case, we hasten the formation of pus by means of *hot compresses*.

As soon as fluctuation occurs, we make a *free incision* through the anterior wall of the sac, or the skin beneath which pus has formed. *After evacuation*, the incision is *kept open* by a strip of gauze which is changed daily, until all inflammatory signs have disappeared and the fluid is no longer purulent. We try to *restore permeability* of the duct, after which the fistula closes spontaneously. If this does not happen after

the duct becomes pervious, we freshen and unite the edges of the opening, or cauterize them with silver nitrate or the electro-cautery, or scrape out the track with a sharp spoon. In some cases it may be advisable to *extirpate the sac*, but never until all acute symptoms have subsided.

CHAPTER VI.

DISEASES OF THE ORBIT.

Anatomy.—The orbit is formed of bony walls having the shape of a quadrilateral pyramid; the apex corresponds to the optic foramen; the base is directed forward and corresponds to the strong, thick, projecting, anterior margin of the orbit. The nasal wall, the thinnest, is formed by the lacrymal bone and the os planum of the ethmoid; it presents in front the groove for the lacrymal sac. The inner walls of the orbits are almost parallel, but the outer diverge considerably from each other from behind forward.

The apex or posterior portion of the orbit presents three *openings* leading to adjacent cavities: (1) the optic foramen, transmitting the optic nerve and the ophthalmic artery; (2) the sphenoidal fissure, transmitting the ophthalmic vein, the nerves for the ocular muscles, and the first branch of the trigeminus; (3) the sphenomaxillary fissure, transmitting branches of the second division of the trigeminus.

Besides communicating with the cavity of the skull by means of the openings at the apex, the orbit is *surrounded by a number of other cavities*. These are the nasal fossæ and accessory cavities—the ethmoidal and sphenoidal sinuses, the frontal sinus, and the antrum of Highmore; these relations are important.

The *contents* of the orbit consist of the eyeball and optic nerve, the ocular muscles, the lacrymal gland, blood-vessels, and nerves; the spaces between these are filled with fat and fasciæ.

The *eyeball* is composed of the segments of two spheres; the anterior (cornea), about 12 mm. in diameter, is the smaller and more prominent; the larger, posterior, corresponds to the sclera. The eyeball measures about an inch in diameter (24.5 mm. from side to side, 24 mm. from before backward, and 23.5 mm. from above downward).

The *orbital fascia* is extensive and presents numerous subdivisions. It serves as *periosteum* to the walls of the orbit (*periòrbita*). A portion closes in the opening of the orbit forming an anterior wall and extending from the margin of the orbit to both tarsi, and to the external and internal tarsal ligaments, thus constituting the *septum orbitale*. Prolongations of the orbital fasciæ surround the muscles and connect them with one another, the lids, and the margins of the orbit.

In addition, a layer of fascia surrounds the globe from the cornea to the posterior part, separating the organ from the orbital fat and form-

ing an articular socket, which permits free movement of the eyeball in every direction. This investment is known as *Tenon's capsule*. The contiguous surfaces of the sclera and of Tenon's capsule are smooth and lined with endothelium. In this manner a lymph space is formed, known as *Tenon's space*, which is continuous posteriorly with the

FIG. 95.—Coronal Section Showing the Orbit and Adjacent Cavities.

supravaginal space surrounding the external sheath of the optic nerve. Where the tendons of the ocular muscles pierce Tenon's capsule, the latter is reflected upon them, becoming continuous with their fasciæ.

The *arteries* of the orbit are derived from the ophthalmic. The *veins* empty into the ophthalmic veins, which pass through the sphenoidal fissure to the cavernous sinus. The *nerves* of the orbit are motor and sensory; the motor nerves, the third, fourth, and sixth, supply the ocular muscles; the sensory nerves are the first and second branches of the trigeminus. The *ciliary ganglion* lies to the outer side of the optic nerve; it receives motor fibres from the third, sensory fibres from the fifth, and sympathetic filaments from the carotid plexus; it gives off the short ciliary nerves which enter the eye at its posterior part. The orbit contains no lymph-vessels or lymphatic glands.

Affections of the Orbit include periostitis, cellulitis, pulsating exophthalmos, distention of adjoining cavities, tumors and injuries.

Exophthalmos (*proptosis*) is a *protrusion of the eyeball* from the orbit (Fig. 96). It is caused by inflammations, tumors and injuries of the orbit, dilatation of adjoining cavities, pul-

FIG. 96.—Exophthalmos.

sating exophthalmos, thrombosis of the cavernous sinus, Graves' disease, and in some cases by paralysis of the recti muscles and tenotomies of these muscles. When of high degree, it may cause *interference with the mobility of the eye, imperfect closure of the lids* (lagophthalmos), with resulting keratitis from exposure, ectropion of the lower lid, *diplopia* (if lateral

displacement is added), and interference with vision from inflammation and atrophy of the optic nerve.

Enophthalmos is the *recession of the eyeball* into the orbit. With the exception of the cases seen in the aged, and in extreme emaciation due to the decrease of orbital fat, it is rare. Other causes are paralysis of the sympathetic, injuries to the orbit causing cicatricial contraction, and fracture of the orbital wall.

ORBITAL PERIOSTITIS.

An inflammation of the *orbital periosteum*, either *acute* or *chronic* in its course, and either *limited* to a portion of the margin of the orbit or *spreading* more deeply.

The *products of inflammation* often consist merely of a *thickening* of the membrane; sometimes there is a *deposit* of bone or gumma (syphilis); there may be the formation of an *abscess*, with or without *caries* or *necrosis* of a part of the wall of the orbit.

Symptoms.—These depend upon whether the affection runs an acute or a chronic course, the part of the orbit involved, and the nature of the products of inflammation.

The most common variety is that attacking the *margin of the orbit*. In such a case there may be no other symptoms than *pain, tenderness* on pressure at the orbital margin, hard immovable *swelling* in this situation, and some swelling of the lids and conjunctiva. Such a case frequently results in complete *absorption* of the products of inflammation; less commonly, periosteal thickening or bony deposit remains. If, on the other hand, there is pus, a periosteal *abscess* is developed at the margin of the orbit, which perforates through the skin, leaving a *fistula* through which the probe detects either bare or necrosed bone. Such a fistula remains open for months until all the dead bone has been extruded, and after it heals there is a depressed *scar* and sometimes ectropion and lagophthalmos.

If the periostitis is *situated more posteriorly*, there will be more pain, and this will be of a deep-seated character. Such cases may result in *absorption* of the products of inflammation, or in periosteal *thickening* or bony deposit. But if such a deep-seated process goes on to the formation of an abscess, it becomes much more serious and presents the *symptoms of orbital cellulitis*, from which it frequently cannot be differentiated. The pus finds its way to the surface, but this may take some time. Cases of this sort, especially if they involve the roof, may be dangerous to life through extension to the cranial cavity and the occurrence of meningitis or cerebral abscess.

Etiology.—*Injuries*, especially infected wounds; *tuberculous diathesis* (in children); *syphilis* (in adults); *rheumatic diathesis*; extension from neighboring cavities or bones; and cold. Rheumatic and syphilitic cases usually run a chronic course and produce periosteal thickening without any tendency to suppuration.

Treatment.—That of syphilis, rheumatism, or tuberculous diathesis. Locally, moist, *warm compresses*. *Incision* as soon as there are any signs of suppuration. Early incision by means of a narrow knife is indicated as soon as we suspect the existence of pus, so as to prevent the extension of suppuration to the brain. The opening is *drained* by means of a strip of

iodoform gauze, until pus no longer escapes. Caries and necrosis may require subsequent operative intervention.

ORBITAL CELLULITIS.

Orbital Cellulitis or *Abscess* is an inflammation of the *cellular tissue* of the orbit, terminating in *suppuration*. It runs an *acute* course, accompanied by marked constitutional symptoms.

Symptoms.—Great *swelling* of the lids, *chemosis*, *exophthalmos*, *impairment of mobility* of eyeball, violent *pain* in the orbit and side of head increased by pressure against eyeball; these local signs are accompanied by *marked constitutional symptoms*, with high fever; cerebral symptoms may be added. *Vision* may not be affected, or it may be reduced or abolished owing to the occurrence of optic neuritis. After these symptoms have lasted about a week *pus appears*, at a certain part of the skin of the lids and perforates, or it may empty into the fornix. After the evacuation of pus, the symptoms rapidly subside and the opening heals.

Complications.—Optic neuritis; less frequently, thrombosis of the retinal vessels; occasionally panophthalmitis. Extension of the process to the brain may be fatal.

Etiology.—1. Injuries and operations followed by *infection*. 2. Extension of inflammation from neighboring parts. 3. Facial erysipelas. 4. Metastasis (pyæmia, puerperal septicæmia, etc.). 5. Cold (idiopathic).

Treatment.—*Hot fomentations*. Early and *deep incision* in the spot where we suspect the abscess to be situated, either through the conjunctiva or through the skin. Even when we do not strike pus, we relieve tension and prepare a route for the subsequent evacuation.

Tenonitis is a rare affection, consisting of *serous inflammation of Tenon's capsule*, and resulting in cure in a few weeks. Its *symptoms* are moderate swelling of the upper lid, chemosis, slight exophthalmos, and limitation of movements of the eye, some pain on motion of eyeball. It may follow a tenotomy of one of the recti muscles, exposure to cold, be

idiopathic, or due to rheumatism. *Treatment* consists of cold or warm fomentations, and the treatment of the rheumatism if present.

Pulsating Exophthalmos.—This term comprises a number of conditions which present the following *symptoms*: Exophthalmos, pulsation of the eyeball and surrounding parts, bruit heard over the eye and forehead, noises in the head, pain, and marked distention of the blood-vessels of the retina, conjunctiva, and lids, and occasionally optic neuritis. Compression of the carotid of the same side causes a diminution or disappearance of the pulsation and bruit. It is most frequently produced by an arterio-venous aneurism due to rupture of the carotid into the cavernous sinus, generally caused by traumatism; it may be due to aneurism of the ophthalmic artery or one of its branches, or of the internal carotid, or to a vascular tumor. The condition may be fatal from hemorrhage. Treatment consists in digital or instrumental compression of the common carotid; if this does not succeed, ligation of this vessel; most cases are cured in this manner.

Distention of Cavities Adjoining the Orbit.—The cavities adjoining the orbit (frontal sinus, maxillary antrum, ethmoidal cells, and sphenoidal sinus) are lined by an extension of the lining of the nose with which they are connected. As a result of catarrhal inflammation or from other causes, these communications may become narrowed or obliterated. The lining membrane of these accessory sinuses continuing to secrete, there soon follows distention with mucous fluid (*dropsy*), or with purulent fluid (*empyema*). The orbit will be encroached upon and the eyeball displaced. The process may also result from *disease* of the lining membrane.

The *frontal sinus* is affected more frequently than any of the others. A *bulging* is noticed at the upper and inner part of the orbit, with or without pain. The thin layer of bone is absorbed and an elastic *swelling* appears. *Treatment* consists in making an *opening* into the frontal sinus through the integument and bone, washing out and *draining* for some time.

Or we may make an opening by way of the nasal fossa and drain in this manner.

Tumors of the Orbit are of *infrequent* occurrence. The *symptoms* will depend upon the size, position, and nature of the tumor. *Exophthalmos* is usually present. The direction of the protrusion and the impairment of motion of the eyeball will be determined by the exact situation of the tumor. Pressure upon the optic nerve may cause optic neuritis and atrophy. When located forward or after it has reached a certain size, the tumor may be felt by the tip of the finger passed between the margin of the orbit and the eyeball. Benign tumors usually grow slowly and frequently give few symptoms; malignant tumors increase in size very rapidly and cause much pain. *Benign* tumors of the orbit include dermoid cyst, aneurism, angioma, pulsating exophthalmos, meningocele, osteoma, and distention of neighboring cavities. *Malignant* tumors are sarcoma and carcinoma.

Injuries of the Orbit include contusions, incised and penetrating wounds, foreign bodies, and fracture of the orbital wall. A prominent sign is *hemorrhage* into the orbit, causing *exophthalmos* and its symptoms, and by pressure, atrophy of the optic nerve. If the wound becomes infected, orbital abscess will develop. In penetrating wounds, foreign bodies, and fractures, the optic nerve may be injured, and as a consequence there will be atrophy. In fractures, emphysema is a common sign. *Fractures* not only affect the orbital margin but occur more deeply, and then may involve the wall of the optic canal and injure the optic nerve; such deep fractures are produced by direct violence, and also indirectly by contrecoup. *Treatment* consists in cleansing and disinfecting the wounds, and endeavoring to extract foreign bodies. During the time that secretions are escaping from the wound, the latter should be kept open.

Congenital Anomalies of the Eyeball are rare; they are usually bilateral. *Anophthalmos* is a small solid or cystic mass occupying the place of the eyeball. *Microphthalmos* consists of an eyeball of diminished size in all diameters. *Buphthalmos* (congenital glaucoma) is an increase in size of the

eyeball with symptoms of glaucoma, usually resulting in blindness (p. 184).

OPERATIONS UPON THE EYEBALL.

Enucleation of the Eyeball.—*The Instruments Required* are: (1) eye speculum (Fig. 328); (2) fixation forceps Fig. (326); (3) toothed forceps (Fig. 327), (4) curved, blunt-pointed strabismus scissors (Fig. 331); (5) two squint hooks (Fig. 330); (6) strong, curved enucleation scissors (Fig. 97); (7) needle holder (Fig. 332); (8) fine, curved needle, and thin black silk.

Operation.—A general anæsthetic is ordinarily given. After introduction of the speculum, the conjunctiva is divided all around the cornea, as close to its border as possible, and dissected back as far as the insertions of the recti muscles. A squint hook is passed beneath the tendon of the internal rectus, and the latter is divided with the strabismus scissors close to its insertion; then the other straight muscles are cut in the same way, together with the subconjunctival connective tissue for some distance beyond the equator. The points of the scissors must always be directed toward the eyeball and the latter stripped as clean as possible to avoid any unnecessary removal of orbital tissue. Instead of commencing with a circumcorneal division of the conjunctiva, we may begin with a tenotomy of the internal rectus and then divide the conjunctiva as we pass from tendon to tendon. The hook is passed around the globe to make sure that the attachments of the muscles have been completely divided. The eyeball is then dislocated forward by pressing the speculum backward,

FIG. 97.—Enucleation Scissors.

and thus the optic nerve is put on the stretch (Fig. 98). The enucleation scissors, closed, are passed between sclera and conjunctiva, feeling for the optic nerve; they are withdrawn a little, slightly opened, and the nerve is divided at a greater

FIG. 98.—Enucleation of the Eyeball.

or lesser distance from the sclera. The eyeball is held between the thumb and index finger of the left hand, and the oblique muscles and other unsevered attachments are divided. The socket is irrigated with a large quantity of mercuric bichloride solution, 1:5,000. The orbit is plugged for a few minutes to control hemorrhage, and the conjunctiva is closed either with a single suture, which is passed through its edge at intervals and tied like the string of a pouch, or with two or three interrupted sutures. The eye is bandaged and the patient kept in bed for a day.

Care should be taken to avoid rupturing the eyeball, since a collapsed globe makes the operation more difficult. Troublesome hemorrhage may occur; it can be controlled by hot water or by a firm bandage. When an eyeball containing a malignant growth is enucleated, as much of the optic nerve as possible should be removed. In rare cases infection of the wound leads to abscess, thrombosis, and even fatal meningitis. The tendency to meningitis is somewhat increased in enucleation of suppurating eyeballs; hence many oculists consider panophthalmitis a contraindication to enucleation, and postpone operation until after the suppurative process has ceased.

The Indications for Enucleation are: (1) Injuries of the ciliary region, when the eye is completely blind, or the traumatism so extensive that the form of the eyeball cannot be

preserved; (2) traumatic iridocyclitis, to prevent or cure sympathetic ophthalmitis; (3) severe pain in a blind eye; (4) iridocyclitis, phthisis bulbi, and glaucoma, when accompanied by severe pain or inflammatory symptoms, and when the eye is blind or is certain to become so; (5) malignant tumors, either intraocular or epiocular (excepting small tumors of the iris which can be entirely removed by iridectomy); (6) anterior staphyloma, if the eye is blind, troublesome, and disfiguring; (7) panophthalmitis; (8) foreign bodies in the eye when they cannot be removed and cause irritation, or the eye is blind.

Evisceration of the Eyeball.—In this operation the cornea and entire contents of the eyeball are removed, the sclera alone remaining.

The Instruments Required are: (1) eye speculum (Fig. 328); (2) fixation forceps (Fig. 326); (3) curved strabismus scissors (Fig. 331); (4) Graefe knife (Fig. 185) or Beer knife (Fig. 53); (5) sharp spoon; (6) needle holder (Fig. 332); (7) small curved needles, catgut and silk sutures.

Operation.—After insertion of the speculum, the eye is transfixed just behind the cornea with a Graefe or Beer knife, which is made to cut its way out at the upper sclerocorneal junction; the other half of the cornea is separated with the scissors. The contents of the eyeball are then removed thoroughly with a sharp spoon, care being taken that nothing but sclera is left. The cavity is irrigated and allowed to fill with blood, or else dried. The scleral edges are brought together in a vertical line with catgut sutures, and the conjunctiva is united horizontally with silk sutures.

Recovery is less rapid than after enucleation, and the pain and reaction are greater; the support for an artificial eye is usually better. The operation may be substituted for enucleation in all cases excepting malignant tumors, foreign bodies, and sympathetic ophthalmitis.

Evisceration with Insertion of an Artificial Vitreous (Mules' Operation).—Following evisceration, after the scleral cavity has been cleansed and hemorrhage checked, a hollow sphere of glass or silver (or some other sub-

stance) is introduced. This ball must not be too large; its introduction is facilitated by slitting the sclera and by the use of a special inserting instrument. The wound is then closed and dressed as after the ordinary evisceration. There is considerable reaction after this operation, and the patient is confined to his room for a week. The stump is undoubtedly superior to that furnished by any other method, but it frequently happens that the ball is extruded.

Artificial Eyes (Fig. 99) are worn after enucleation and evisceration, for cosmetic purposes and to fill out the cavity

FIG. 99.—Artificial Eyes. *a*, Outer Surface; *b*, Inner Surface; *c*, Section of Shell Eye; *d*, Section of Snellen ("Reform") Eye.

left between the lids. They can be worn as soon as the socket is free from inflammation, usually after several weeks. The artificial eye should be washed frequently, and must be removed every night. After a year its surfaces and edges become roughened, and it must be replaced by a new one. When there is a stump of good size, a shell-shaped artificial eye may be indicated; but with a small stump or after enucleation, the more modern Snellen "reform" artificial eye gives better cosmetic effect; the latter has a certain thickness and is hollow.

CHAPTER VII.

DISEASES OF THE CONJUNCTIVA.

Anatomy.—The conjunctiva is a thin layer of mucous membrane which lines the eyelids and is reflected on to the eyeball, forming a sac, the *conjunctival sac* (Fig. 172). We distinguish three divisions: (1) The *palpebral* conjunctiva, covering the under surface of the lids; (2) the *ocular or bulbar* conjunctiva, coating the anterior portion of the eyeball; and (3) the *fornix*, the transition portion, forming a fold between lid and globe. The conjunctiva differs somewhat in structure in each of these portions.

The *palpebral conjunctiva* is thicker than the other portions. In the greater part of its extent it is closely adherent to the subjacent tarsus, allowing the Meibomian glands to be seen through it. Its surface is smooth, but presents a number of minute projections, or *papillæ*. It is covered with cylindrical epithelium. Its stroma is of an adenoid character, containing a large number of lymph corpuscles, which may in some cases be collected into small rounded masses (lymphoid follicles). It is a disputed question, however, whether these are normal or are the result of pathological processes. Numerous mucous glands are also found.

The *conjunctiva of the fornix* is similar in structure to that of the lids. It constitutes a very loose fold (*retrotarsal fold*), insuring great freedom of movement to the eyeball. It is richly supplied with blood-vessels. This and its lax condition explain its liability to marked swelling in inflammations of the conjunctiva. It has opening into it the lacrymal ducts and numerous mucous glands.

The *bulbar conjunctiva*, thin and transparent, covers the anterior surface of the eyeball, being loosely attached to the sclera by connective tissue (*episcleral tissue*), with the exception of the margin representing the boundary between cornea and sclera (*limbus*), where it is firmly adherent. In structure it resembles the rest of the conjunctiva but contains no glands. It is covered with laminated pavement epithelium which is continued uninterruptedly over the cornea, and constitutes its outer layer. Near the inner canthus it forms a crescentic fold (*plica semilunaris*), the rudiment of the nictitating membrane or third eyelid of the lower animals.

The *vascular supply* of the conjunctiva is derived from the blood-vessels of the fornix—the *posterior conjunctival* (derived from the palpebral) and from the *anterior ciliary*. The latter pass forward along the

recti muscles and pierce the sclera near the limbus to reach the interior of the eye, giving off one set of branches which form *vascular loops* surrounding the cornea and supplying it with nourishment, and another set (*anterior conjunctival*), which pass backward in the conjunctiva and anastomose with the posterior conjunctival. This arrangement, together with the posterior ciliary arteries and the retinal system of vessels, constitutes the entire vascular system of the eye. Thus the bulbar conjunctiva presents two vascular systems—the posterior conjunctival and the anterior ciliary. The nature of the injection in any given case is of some value in locating the seat of the congestion.

The *nerves* of the conjunctiva, branches of the fifth, terminate in end-bulbs, and are especially abundant in the palpebral portion. *Lymphatic vessels* are found in considerable numbers in the conjunctiva, forming a superficial and a deep layer.

Pinguecula is a small, slightly raised *spot of yellowish color* situated at the inner and outer sides of the cornea, especially marked in *old people*. It is not formed of fat as its name implies, but of *connective-tissue* thickening of the conjunctiva. It never calls for interference.

Conjunctival and Ciliary Injection.—The differences between conjunctival and ciliary or circumcorneal injection (Plate VII) are as follows:

Conjunctival Injection.

1. Derived from posterior conjunctival vessels.

2. Accompanies diseases of the conjunctiva.

3. More or less muco-purulent or purulent discharge.

4. Most marked in fornix conjunctivæ.

5. Fades as it approaches the cornea.

6. Bright, brick-red color.

7. Composed of a network of coarse, tortuous vessels, anastomosing freely, and placed superficially, so that the meshes are easily recognized.

8. Can be moved with the conjunctiva by pressure on lower lid.

Ciliary Injection.

1. Derived from anterior ciliary vessels.

2. Accompanies diseases of the cornea, iris, and ciliary body.

3. Often lacrymation, but no conjunctival discharge.

4. Most marked immediately around the cornea; hence called "circumcorneal."

5. Fades toward the fornix.

6. Pink or lilac color.

7. Composed of small, straight vessels, placed deeply, so that the individual vessels cannot be recognized easily, but are seen indistinctly as fine, straight lines radiating from the cornea.

8. Cannot be displaced by movement of the conjunctiva.

PLATE VII.

FIG. 100.—Conjunctival Injection.

FIG. 101.—Circumcorneal (Ciliary) Injection.

FIG. 102.—Ciliary and Episcleral Injection.

FIG. 103.—Subconjunctival Hemorrhage.

Figs. 100-103.—Types of Conjunctival and Ciliary Congestion.
Subconjunctival Hemorrhage.

In severe forms of diseases of the anterior part of the eye these two types of congestion are often found *associated*, as we would expect when we remember that the two systems of vessels anastomose freely.

When very pronounced, particularly when there is much venous congestion, ciliary injection assumes a *violet* color. A form of injection of this sort involves the *episcleral* tissue between the equator of the eyeball and the cornea, presenting a deeply placed, violet-colored patch seen in scleritis and glaucoma (Fig. 102, Plate VII).

Subconjunctival Hemorrhage results in bright or dark red patches involving more or less of the bulbar conjunctiva (Fig. 103, Plate VII), unaccompanied by inflammatory symptoms. *Ecchymosis* is seen after injuries, operations, and inflammations of the eyeball. It is frequently observed in old persons with brittle blood-vessels, being excited by various straining efforts, and in children after whooping-cough. It is of *no importance* and becomes *absorbed* within a week or two.

CONJUNCTIVITIS.

Inflammations of the conjunctiva are known as *conjunctivitis*, or *ophthalmia*. The *varieties* are:

1. Catarrhal: (a) acute, (b) chronic, (c) follicular.
2. Purulent; (a) ophthalmia neonatorum, (b) gonorrhœal.
3. Membranous; (a) non-diphtheritic or croupous, (b) diphtheritic.
4. Granular or trachoma.
5. Phlyctenular.

ACUTE CATARRHAL CONJUNCTIVITIS.

An acute catarrhal inflammation of the conjunctiva accompanied by *mucoid* or *mucopurulent discharge*. It is also known as *acute mucopurulent* and *acute simple conjunctivitis*.

Objective Symptoms.—The palpebral conjunctiva and that of the fornix are of a brilliant *red* color and *swollen* (Fig. 112, Plate IX). There is slight congestion of the bulbar conjunctiva; but in severe cases this may become marked, and

there may be added œdema of the bulbar conjunctiva (chemosis), small conjunctival hemorrhages, and œdema of the lids. The *secretion*, *increased* in amount and *altered* in character, varies according to the severity. In mild cases, it is *mucoid*; in severer forms, it is *mucopurulent*; in very marked examples, the amount of pus may be so considerable that for a day or two we may be in doubt whether the disease is not the beginning of a purulent inflammation. The secretion accumulates during the night and dries upon the edges of the lids during sleep.

Subjective Symptoms.—*Itching* and *smarting* sensations referred to the lids, which feel hot, heavy, and as though sand or a foreign body were underneath. There is more or less photophobia. There may be some blurring of sight when the altered secretion lies upon the cornea. The symptoms are usually worse toward evening; they vary in severity with the degree of inflammation. The affection may be limited to one eye, but usually *both eyes* are implicated, either from the start or after two or three days.

Course.—Most patients get well in a *few days*, or in a week or two, even without treatment. Sometimes the acute symptoms subside and a chronic catarrhal conjunctivitis remains. Blepharitis may be present. In severe cases small, grayish infiltrations may form at the corneal margin. The coalescence of a number of these may cause a marginal ulcer, which is usually unimportant, superficial, and heals readily, but occasionally becomes deep and serious. Rarely iritis occurs as a complication.

Etiology.—The disease occurs at *all ages* and at all times during the year, but is most common in the *spring and autumn*. The causes may be divided into: 1. *Mechanical*—foreign bodies, exposure to wind, dust, smoke, etc. 2. *Epidemic*—in spring and autumn and depending upon some atmospheric condition (the presence of certain micro-organisms). 3. *Infection*—through contact with fingers, towels, handkerchiefs, etc., of patients suffering from the disease. The discharge is *contagious*, especially when free and containing much pus; hence the affection often presents a number of examples in the

PLATE VIII.

same household or school. 4. *Exanthemata*, accompanying or following measles, scarlatina, and smallpox. 5. *Associated* with coryza, rose cold, hay fever, and grippe.

Clinical Varieties.—Certain forms of this disease are distinguished by qualifying adjectives, indicating the etiology.

Traumatic Conjunctivitis is the name often given to acute catarrhal conjunctivitis when excited by the presence of a *foreign body* or by *traumatism*. Under this head are included the forms of conjunctivitis due to *intense light*, for example the electric arc light or that used in electric welding (*electric ophthalmia*), and that produced by reflection from snow (*snow blindness*). In such cases there are symptoms of conjunctivitis, and, in addition, marked photophobia, lacrymation, intense smarting of the lids, contraction of the pupil, and sometimes œdema of the lids and superficial ulceration of the cornea.

Lacrymal Conjunctivitis accompanies dacryocystitis; it is most frequently limited to the inner third of the palpebral and ocular conjunctiva; it is caused by the purulent secretion from the inflamed lacrymal sac, which contains streptococci (Fig. 108, Plate VIII).

Exanthematous Conjunctivitis, when associated with the exanthemata; most commonly seen in measles.

Acute Epidemic Conjunctivitis, popularly known as "*pink eye*," is a form of acute catarrhal conjunctivitis occurring most frequently in the *spring* and *autumn*, in which the symptoms are apt to be *marked* and the discharge is *profuse*. The contagious element is the Koch-Weeks bacillus or the pneumococcus (Plate VIII).

Other Clinical Varieties of acute catarrhal conjunctivitis have been classified according to the *micro-organism* which seems responsible for the inflammation. One form, caused by the diplobacillus of Morax-Axenfeld (Fig. 107, Plate VIII) is subacute, obstinate, and presents but moderate subjective symptoms. Another, which clinically resembles acute epidemic conjunctivitis, presents an abundance of pneumococci (Fig. 105, Plate VIII) in the discharge. In a third variety, streptococci (Fig. 108, Plate VIII) are found in considerable

numbers. Staphylococci are present in greater or lesser numbers in all forms of conjunctivitis.

Follicular Conjunctivitis is considered by some authorities as a variety of *acute catarrhal conjunctivitis*, by others as a form or stage of *trachoma*. It will be described separately.

Treatment.—Though the disease tends to get well without interference, treatment reduces the duration and prevents the change into chronic conjunctivitis. *Iced compresses* should be applied for from fifteen minutes to an hour, three times a day. The conjunctival sac should be *irrigated* several times a day with *salt* solution (3 i. to O i.), or saturated solution of *boric acid*. A *bland ointment* (vaseline or boric-acid ointment) is applied to the edges of the lids at night, to prevent them from becoming glued together during sleep. A twenty-five-per-cent. solution of *argyrol* should be applied to the everted conjunctiva daily, as long as the discharge is abundant. The patient is cautioned concerning the *contagiousness* of the discharge.

If the disease shows a tendency to become obstinate or chronic, *weak astringent solutions* are indicated (zinc, alum, potassium chlorate, silver nitrate), accompanied with an occasional application of one-per-cent. silver-nitrate solution or the alum stick to the everted lids.

CHRONIC CATARRHAL CONJUNCTIVITIS.

A chronic catarrhal inflammation of the conjunctiva, presenting similar symptoms to those found in the acute form, but associated with only *slight changes* in the quantity and quality of the normal *secretion*. It is also known as *chronic simple conjunctivitis*.

Objective Symptoms.—The conjunctiva of the lids is *reddened* and smooth; in old cases it may be *hypertrophied* and *velvety*. The *secretion* is usually but *slightly altered*, and there is very *little increase*; there may be enough to make the eyelids stick together in the morning or to present some dried secretion at the inner canthus. There is apt to be some *excoriation* at the outer angle (*angular catarrh*). In some cases there appears to be less than the normal amount of secretion (*dry catarrh*).

Subjective Symptoms are the same in kind as in the acute form: Itching, burning, dryness, feeling of sand or foreign body, heavy feeling in lids, some sensitiveness to light, and the eyes tire easily. These symptoms are worse at night.

Course.—The disease is probably the most common of ocular affections. It usually occurs in adults, and frequently in old persons. It is apt to be of lengthy duration.

Complications.—*Blepharitis* is frequently present. Eczema of the lower lid and eversion of the inferior punctum occur not infrequently, and sometimes ectropion and corneal ulceration.

Etiology.—It may be the sequel of an acute catarrh. It may be caused by improper hygienic surroundings, vitiated atmosphere (overcrowding), irritating atmosphere (smoke, dust), insufficient sleep, late hours, alcoholic excesses, exposure of the conjunctiva in ectropion, eye-strain, overuse, local irritation such as trichiasis, chronic dacryocystitis, etc. It is usually bilateral, but when due to local irritants it may be unilateral.

Treatment.—We must endeavor to remove the cause of the inflammation. Locally: Astringent solutions (zinc, borax, alum, tannic acid, silver nitrate gr. $\frac{1}{10}$ or $\frac{1}{8}$ to $\frac{2}{3}$ i.); ointments of the yellow oxide and ammoniated mercury; silver nitrate, one per cent., brushed on the everted lids once a week; the occasional application of the alum or sulphate of copper stick; bland ointments to the edges of the lids at night to prevent gluing together and excoriations. As in all chronic catarrhal affections, the remedies must be changed from time to time.

FOLLICULAR CONJUNCTIVITIS.

This disease, also known as *Follicular Catarrh*, may be regarded as an obstinate form of catarrhal conjunctivitis, with the occurrence of "follicles" upon the lower lid (Fig. 114, Plate IX).

Objective Symptoms.—In addition to the appearances found in catarrhal conjunctivitis, the conjunctiva of the lower lid presents a variable number of small, pale, round granules, about the size of the head of a pin; if many are present they

may be arranged in rows; they are most abundant in or *near the fornix*. Occasionally some are found on the upper lid. These follicles consist of small masses of *adenoid tissue*, in which respect the pathology resembles that of trachoma. On this account, and also because the secretion may excite trachoma in another eye and the disease may terminate in granular conjunctivitis, some authorities consider follicular catarrh to be a stage of trachoma.

Subjective Symptoms are identical with those of *catarrhal conjunctivitis*. In many cases patients do not complain of any symptoms and the existence of the granulations is discovered accidentally.

Course.—The disease may be either *acute* or *chronic*. In either case the course is *obstinate*; in chronic cases the follicles may persist for months and even years. It is sometimes difficult, especially in acute cases, to differentiate between follicular catarrh and granular conjunctivitis, and we may have to await the results of several weeks' treatment in order to decide definitely. The *follicles*, in this disease, *disappear after a time*, leaving the conjunctiva in a natural condition, and they affect principally the *lower lid*; in trachoma, on the other hand, there are permanent changes in the conjunctiva, and when the granulations are confined to one lid, it is the upper which is involved.

Etiology.—It occurs most frequently in *children* and in young persons; it is often found in schools and asylums. The exact cause is not definitely known. *Contagion* seems responsible in some cases. *Poor hygienic surroundings*, especially indoor life, seem to predispose. The various causes of catarrhal conjunctivitis act as exciting factors.

Treatment.—The same as that given for acute and chronic *catarrhal conjunctivitis*. It is of special importance to correct any interference with the general health and to place such children under the *best hygienic surroundings*. Locally, the *ointment of the yellow oxide of mercury*, applied within the conjunctival sac, is a favorite remedy. The occasional use of one-per-cent. solution of *nitrate of silver* or of the *sulphate of copper* stick may be of service. When the patient no longer

complains of any symptoms and the follicles persist, they may be allowed to remain and treatment discontinued.

Purulent Conjunctivitis is an *acute* purulent inflammation due to *contagion from gonorrhœal virus*. The contagious elements are the *gonococci* (Neisser); they occur in gonorrhœal secretion, are found in the pus cells and conjunctival epithelium, and are arranged in pairs (diplococci) and generally in colonies (Fig. 104, Plate VIII). The disease is also known as *acute blennorrhœa of the conjunctiva*.

Clinical Varieties : (1) *Adult Purulent Conjunctivitis* or Gonorrhœal Ophthalmia or Conjunctivitis. (2) *Infantile Purulent Conjunctivitis* or Ophthalmia Neonatorum (occurring in the *new-born*).

ADULT PURULENT CONJUNCTIVITIS OR GONORRHOEAL OPHTHALMIA.

Symptoms.—*First Stage, Infiltration.*—After a period of incubation varying from a few hours to two or three days (short in severe cases), there occur *great swelling and redness of the lids*, so that the latter cannot be opened voluntarily and can be separated only with difficulty. The *conjunctiva* of the lids and fornix is *intensely swollen and reddened* and is uneven; there is *chemosis* (œdema of the ocular conjunctiva [Fig. 110], causing it to swell up around the cornea). The secretion is at first serous, somewhat colored with blood, and containing a little pus. The eye is *tender* to touch. The patient complains of a hot, smarting *pain* in the eye and a dull aching in the brow and temple. There are some constitutional disturbance, slight fever, and some swelling of the preauricular gland. This stage lasts about two days and is followed by the

FIG. 110.—Chemosis of the Conjunctiva.

Second Stage, the Stage of Purulent Discharge.—The

swelling of the lids and conjunctiva and the chemosis diminish and the eye becomes less tender. A very *profuse purulent discharge* appears and escapes continually from between the lids. This condition continues for two or three weeks, all symptoms gradually diminishing.

Third Stage, Convalescence or Papillary Swelling.—The eye may return to a *normal* condition in two or three weeks. More frequently, however, there is a stage of *papillary swelling*, a chronic inflammation of the lids; the palpebral and retrotarsal conjunctiva remaining thickened and red and presenting, especially over the tarsus, an *uneven granular or velvety appearance*, with hyperæmia of the ocular conjunctiva.

Course.—The disease occurs in *various degrees of severity*. Cases in which there is slight infection, or in which the disease is acquired from a chronic gonorrhœa (gleet) are the mildest. The very intense cases have probably been acquired through contagion from the secretion of a very virulent gonorrhœa, and especially from contamination during the early stages. In these very severe forms there may be a deposit of croupous membrane upon the conjunctiva.

Etiology.—The disease is always acquired through infection from *gonorrhœal secretion*, either *directly*, the fingers of the patient transferring the virus from the genitals, or *indirectly* by means of contaminated towels, etc.

Complications.—A very frequent and important complication is *corneal ulceration*. This begins with a circumscribed grayish *infiltration*, becoming yellow and breaking down, so that *ulcers* are formed. The ulcers vary in situation, size, and course. They may be central or marginal; the latter may be confluent, so as to form an annular ulcer. The ulcers may *perforate* and this be followed by cicatrization with or without incarceration of the iris, staphyloma, and other sequelæ of corneal ulceration. Panophthalmitis may result. Severe and early involvement of the cornea is most common in intense attacks; in such cases, serious and permanent damage to the eye is very common.

Prognosis depends upon the *severity* of the case, and upon the *behavior of the cornea*. It is always *grave*.

Treatment.—*Prophylactic*: Great precautions must be observed to *prevent infection* of the eyes of the physician, nurse, and attendants through spurting of the discharge during examination or treatment; *protecting glasses* should be worn whenever exposed to this risk. Contaminated *fingers* must be carefully *disinfected*. *Materials* which have been used for cleansing the eye must be *burned*.

The non-affected eye should be protected from infection by the application of *Buller's shield* (Fig. 111). This consists of a watch glass, securely held in place by adhesive plaster applied to the side of the nose, the cheek, and forehead. The junction of skin and plaster is sealed by a layer of collodion. The centre of the glass is left uncovered by plaster to permit inspection of the eye, and a small part of the outer margin of the watch glass is usually left free in order to allow air to enter and contribute to the comfort of the shielded eye.

FIG. 111.—Buller's Shield.

Treatment of the First Stage: *Iced compresses* are used continuously, day and night. The eye must be carefully *cleansed* and the *secretion removed* as rapidly as it forms. When very abundant, this will be necessary every quarter or half an hour. For this purpose a *saturated solution of boric acid* is most frequently employed, being allowed to trickle in between the lids from a piece of absorbent cotton dripping with the remedy, or poured in from an undine (Fig. 350); then the secretion which has been washed out is gently wiped off from the margins of the lids.

The iced compresses may be used continuously at first. But when the tense, reddened, and swollen condition of the lids becomes less marked the *application of cold must be reduced* to every other hour, or every third hour; too much refrigeration interferes with the nutrition of the cornea.

When the cornea is involved, we must carefully gauge the amount of cold so as not to use an excess. In the *later stages*, when there is little swelling, and corneal infiltration or ulceration exists, *hot applications* may be used in order to improve nutrition by stimulating the flow of blood to the part.

Instead of boric acid, other cleansing and antiseptic solutions are often used: Mercuric bichloride (1:5,000, or 1:10,000), sodium chloride (0.75 per cent.), sterilized water, permanganate of potassium (1:500), etc. The instillation of a few drops of a twenty-five-per-cent. solution of *argyrol* or *protargol* every three hours is of great value.

In the initial stage, if the disease be very severe, from three to six *leeches*, applied to the corresponding temple, may be of service. Occasionally there is so much *tension* that the eye cannot be cleansed on account of the difficulty in separating the lids, and in addition harmful pressure is exerted upon the eyeball; in such cases it may become necessary to widen the palpebral fissure by a division of the external canthus (*cantotomy*, p. 46).

Treatment of the Later Stages: When the lids have lost their swollen and angry appearance and the discharge begins to diminish, a one- or two-per-cent. solution of *nitrate of silver* is *brushed* upon the *everted conjunctiva* once a day. This may be done even though the cornea is implicated. It is continued until the patient is well, or until the papillary swelling has persisted for some time. Then, if silver no longer exerts a favorable influence, we may apply glycerole of *tannin* (five to ten per cent.), the *alum* stick, or *sulphate-of-copper* pencil once a day.

The treatment of *corneal complications* resembles that of infected corneal ulcers, and is described in the next chapter.

INFANTILE PURULENT CONJUNCTIVITIS OR OPHTHALMIA NEONATORUM.

An *acute purulent* conjunctivitis occurring in the *new-born*, presenting similar symptoms, complications, and course, and requiring the same treatment, as in the gonorrhœal ophthalmia of adults.

Symptoms.—The period of incubation being the same as in adults, the first symptoms are usually noticed on the *second or third day after birth*; when the onset is later than the third or fourth day, infection has taken place subsequent to the birth of the child.

The symptoms (Fig. 113, Plate IX) are the *same in kind as those of gonorrhœal ophthalmia*, but are often less severe, and more apt to be limited to the palpebral and retrotarsal conjunctiva. *Both eyes* are usually involved. The *cornea* is implicated in a much smaller proportion of cases, especially if the affection is treated from the start. If the case is seen early, before the cornea is affected, and properly managed, this part very often escapes destruction or serious damage.

Prognosis, therefore, *with early and proper treatment is generally favorable*.

Etiology.—*Infection by gonorrhœal secretion from the genitals of the mother during parturition*. In rare cases, infection occurs before birth. Sometimes it occurs *subsequent* to the birth of the child, through infection from sponges, napkins, towels, or the fingers of the nurse, which have been in contact with the genitals of the mother.

It is a question whether every case of ophthalmia neonatorum is produced by infection from a gonorrhœal vaginitis. The great majority of cases are undoubtedly of gonorrhœal origin. It is probable, however, that a few cases result through infection from simple catarrhal (non-gonorrhœal) secretion; such exceptional cases run a mild course and are not usually complicated by corneal ulcers.

Treatment is similar to that employed in adult purulent conjunctivitis: *Iced compresses* and *frequent cleansing* from the start; *argyrol* or *protargol* (twenty-five per cent.) instillations; daily applications of one- or two-per-cent. solution of *nitrate of silver* after the swelling and redness have diminished and the discharge begins to be less profuse, continued throughout the stage of papillary swelling.

In applying the *iced pads*, we must be careful *not* to use them *too continuously*, as soon as the redness and swelling begin to diminish. In adults, the sensations of the patient

guide us to a certain extent, and we use the pads less often when they no longer feel grateful, as happens when the redness and swelling subside. In infants, we cannot receive this information; hence great care must be used not to injure the cornea by excessive cooling, especially if there is corneal infiltration; in such cases, *hot compresses* are often substituted for the cold.

The general health of the infant must be looked after, since enfeebled conditions render treatment unsatisfactory and favor corneal complications.

Credé's Method of Prophylaxis.—Ophthalmia neonatorum is practically *preventable*. Through the adoption of Credé's method, its occurrence has been made infrequent in lying-in asylums and in private practice among the better classes. The method consists in *cleansing* the eyes of the child with water immediately after birth, and instilling one drop of a *two-per-cent. solution of nitrate of silver* into each eye; this often causes a slight redness of the conjunctiva for a day or two. It acts by *destroying any gonococci* which may have entered the conjunctival sac. Antiseptic irrigation of the vagina of the mother before delivery is also useful as a prophylactic measure.

Catarrhal Conjunctivitis in the New-Born.—Sometimes we meet with a slight catarrhal conjunctivitis in the new-born, lasting a few days and presenting merely hyperæmia, slight swelling, and a little mucoid discharge. These are not examples of ophthalmia neonatorum. But at the start we may be in doubt whether they are not purulent cases, and it will be safer to treat them as such until the character of the inflammation becomes certain. In such cases, bacteriological examination of the conjunctival discharge is of great value.

Membranous Conjunctivitis.—This term comprises two clinical varieties: 1. *Diphtheritic Conjunctivitis*, and 2. *Non-diphtheritic* or *Croupous Conjunctivitis*. This subdivision is based upon the *clinical pictures* presented. The bacteriological peculiarities of the exudation may be, and often are, identical.

DIPHTHERITIC CONJUNCTIVITIS.

An *acute* inflammation of the conjunctiva, associated with exudation and *infiltration*, purulent discharge, with tendency to *necrosis* of the involved tissues. The disease is rather rare and occurs in *children*. It spreads by *infection*. The secretion contains the Loeffler bacillus (Fig. 109, Plate VIII) and is *contagious*.

Symptoms.—The *lids* are very much *swollen*, *reddened*, hot, and tender. The *conjunctiva* of the lids and fornix is intensely *inflamed* and is covered by a grayish-yellow *exudation*, which also *infiltrates* the underlying tissues. In this way the lids become *hard* and cannot be everted. The exudation causes compression, and, as a result, there is a tendency to *sloughing* of the infiltrated parts. Besides this fibrinous exudation, there is a *discharge* of a *thin*, cloudy fluid. With these local signs, there are the prostration and other *constitutional symptoms* of diphtheria, and often local evidences of the disease in other parts of the body.

At the end of a week the exudation disappears, partly through *absorption*, partly through necrosis and *sloughing*, causing a loss of substance covered by *granulations*. The secretion now becomes more *abundant* and *purulent*.

The defects in the lining of the lid gradually cicatrize, this process causing various *deformities*: symblepharon, trichiasis, and entropion. There is frequently *corneal ulceration*. When the diphtheritic process is severe, the cornea is seriously involved and sight is always lost.

The Prognosis in regard to sight is *always serious*; in regard to life, it depends upon the constitutional effects and general condition of the child.

Treatment.—*Prophylaxis*: The precautions described under gonorrhœal ophthalmia must be employed in this disease, to protect physician, nurse, and attendants. Besides being contagious, the disease is infectious; hence the patient should be *isolated*; other children must be removed. The *second eye* must be *shielded*.

Treatment of the Affected Eye: Careful cleansing with weak

antiseptic solutions (boric acid, corrosive sublimate). *Cold compresses* may be applied, but must be used cautiously on account of the enfeebled circulation. After a short period, *hot compresses* are used. When the exudation has separated, we apply a one-per-cent. solution of *nitrate of silver*. We endeavor to *prevent sequelæ* due to cicatrization, by frequent separation of the lids from the globe, and by keeping the two surfaces apart by a roll of absorbent cotton smeared with some bland ointment. Corneal ulceration must be treated as described in the next chapter.

Constitutional: We must remember that the eye affection is merely the local manifestation of a constitutional disease. Hence the general treatment of diphtheria must be carried out. Injections of *antitoxin* are of great value, producing a rapid improvement in the local as well as the general condition.

CROUPOUS CONJUNCTIVITIS OR NON-DIPHTHERITIC MEMBRANOUS CONJUNCTIVITIS.

A form of inflammation in which there is the deposit of an *exudation upon the surface* of the conjunctiva, upon which it hardens into a *membrane*. There is *no infiltration* into the tissues; this constitutes the essential difference between croupous and diphtheritic conjunctivitis. Bacteriological examination may reveal the Loeffler bacillus and other micro-organisms, and these may be identical with those found in diphtheritic membrane. There are, however, *no constitutional symptoms* such as accompany diphtheria.

Symptoms.—Those of *catarrhal conjunctivitis*. A *fibrinous membrane* forms upon the palpebral conjunctiva; when this exudation is pulled off, a raw surface presenting a few bleeding points is seen; under such circumstances the membrane re-forms.

Etiology.—It may be caused by *irritants* (mechanical, chemical, or thermic), or by the action of various *micro-organisms*. Examples of the former are nitrate of silver, acids, lime, molten lead, burns, and injuries in general.

Treatment.—That of *catarrhal conjunctivitis*. As soon as

the membrane shows no tendency to re-form, applications of one-per-cent. solution of *nitrate of silver* are useful.

GRANULAR CONJUNCTIVITIS, TRACHOMA OR GRANULAR LIDS.

An inflammation, generally of lengthy duration, accompanied by *hypertrophy of the conjunctiva* and the formation of "*granules*," with subsequent *cicatricial changes*. It is a *common* disease and occurs at *all ages*. There is more or less secretion, which is *contagious*. It is a very important affection on account of its disastrous complications and sequelæ, which are responsible for many cases of partial or total blindness.

Subjective Symptoms.—More or less photophobia, lachrymation, itching and burning sensations, feeling of foreign body, pain, and visual disturbance. In a good many cases there are no subjective symptoms.

Objective Symptoms.—There may be *swelling* of the lids, narrowing of the palpebral aperture, and *drooping* of the upper lid (from weight and swelling), but very often these external evidences are absent. There is a variable amount of muco-purulent *discharge*, marked in recent cases, scanty in chronic forms. The *conjunctiva* of the tarsus and fornix is *reddened*, thickened, and uneven, on account of *hypertrophy* and the occurrence of *granules*. The ocular conjunctiva is often somewhat injected.

Forms.—Basing the subdivision upon variations in local appearances, we distinguish three forms: (1) papillary, (2) granular, and (3) mixed.

(1) *Papillary Form.*—A large number of small elevations (*papillæ*) are seen upon the greatly *thickened conjunctiva*, giving the latter a velvety appearance, or, if the *papillæ* are larger, a granular aspect. This form affects only the *tarsal conjunctiva*, and usually only the *upper lid*. The *papillæ* are caused by the hypertrophied conjunctiva being thrown into folds, covered by an increase in epithelium, the connective-tissue interior being infiltrated with cells.

(2) *The Granular Form* presents a preponderance of tra-

choma granules (Fig. 115, Plate IX). These are grayish or yellowish, rounded, *translucent bodies* showing through the conjunctiva. They may be *small and rounded*, larger and *warty*, or *flattened* and succulent. They are present principally in the *fornix*, and when numerous are arranged in rows. In the tarsal conjunctiva they are less numerous, smaller, and less distinct, being hidden by the papillæ. Occasionally, trachoma granules are formed upon the semilunar folds and the bulbar conjunctiva. The granules are rounded *collections of lymph corpuscles in a connective-tissue reticulum*, resembling what we see in Peyer's patches in the intestines; they may present an incomplete capsule in old cases.

(3) *The Mixed Form* represents the *common* condition, the papillary and granular varieties being almost always found together, the former more prominent in the palpebral conjunctiva, the latter predominating in the fornix.

Course.—The process *progresses* up to a certain point, and is then followed by *cicatricial changes* in the conjunctiva (*cicatricial stage*). This cures the trachoma, and the *papillæ and granules disappear*; but the conjunctiva does not return to a normal condition, the cicatricial changes and contraction leading to certain *sequelæ*; the seriousness of the latter depends upon the severity of the process and the amount of hypertrophy and subsequent cicatrization. In the tarsal conjunctiva the cicatricial process causes narrow, whitish *bands and scars* (Fig. 129, Plate X), sometimes a network; in advanced and severe cases the entire surface may be replaced by a pale, smooth *cicatricial membrane*. In the fornix, cicatrization changes the conjunctiva into a pale, bluish-white membrane, and as a result of contraction the *transition fold is shortened* or disappears.

Clinical Varieties.—Clinically, trachoma presents a number of varieties. Occasionally the invasion is acute, *acute trachoma*, and accompanied by marked inflammatory symptoms and profuse purulent discharge; such cases resemble purulent conjunctivitis. The finding of gonococci in the secretion and the presence of the trachoma granules serve to differentiate, but frequently the swelling hides the latter; we may have to

FIG. 117.—Episcleritis.

wait several days, until the swelling subsides somewhat, before we can decide.

Frequently the disease begins *insidiously*; it may exist unknown for months, before the subjective symptoms become annoying. *Most cases* of trachoma are *chronic* in their course, and the duration is months or years.

H. Knapp divides chronic trachoma into (1) *inflammatory trachoma*, with inflammatory symptoms, very contagious, leading to cicatrization of the conjunctiva and various sequelæ when unchecked; and (2) *simple or non-inflammatory trachoma*, in which, with moderate or marked deposition of granulations of the granular form in the palpebral and retro-tarsal portions of the conjunctiva of both lids, there are but slight or no symptoms of irritation or discomfort; the latter form he believes to be non-contagious.

Besides these differences in the intensity of the inflammatory symptoms, there are great variations in the amount of change in conjunctiva and cornea. There are *mild cases*, in which there are but little hypertrophy and insignificant cicatricial changes in the conjunctiva, so that afterward we can scarcely be sure that trachoma has existed; such mild cases usually remain free from corneal complications.

In *moderate and severe cases* there always remain permanent *cicatricial changes*, which enable us to diagnose the previous existence of trachoma. When the cornea is implicated, the case is always a *serious* one.

Trachoma does not always progress uninterruptedly; there are often *intermissions* and *exacerbations*. *Relapses* are quite frequent, especially when treatment has been discontinued too soon.

Complications.—The most frequent are pannus and corneal ulceration, both causing disturbance of sight.

Pannus consists of a newly formed *vascular tissue*, which usually covers the upper part of the cornea (Fig. 129, Plate X). The affected portion of the cornea presents a *cloudy* appearance, and is grayish and translucent; its surface is *uneven* and *vascularized*, the blood-vessels springing from the conjunctival vessels at the limbus. The process advances

until it covers the *upper half* of the cornea. Finally, the entire cornea may be covered, in which case *vision is reduced* to perception of light. Unless subsequent changes occur, complete retrogression is possible, so that the cornea can become transparent again. In marked cases *iritis* is apt to develop. Pannus is not merely due to mechanical irritation, but to a change similar to that which occurs in the conjunctiva.

Ulcers of the Cornea occur with or without pannus. They leave opacities, which interfere with vision according to their seat and density.

Sequelæ.—Complete cure is usually effected in the mildest cases alone, or in more severe forms only when they are subjected to early treatment. Sequelæ are very common, affect the conjunctiva, cornea, and lids, and produce permanent disability of the eye.

1. *Trichiasis and entropion* occur as a result of cicatricial contraction of the conjunctiva with curving of the tarsus; they are more pronounced in the upper lid. As a result of this distortion of the lid with consequent changes in the position of the cilia, there is mechanical interference with the cornea, causing ulceration.

2. *Ectropion* (usually of the lower lid) follows in some cases, as a result of hypertrophy of the conjunctiva and contraction of the orbicularis.

3. *Symblepharon* results from cicatricial contraction of the conjunctiva; when considerable, there is obliteration of the fornix. This condition restricts the movements of the eyeball.

4. *Corneal opacities* result from pannus and corneal ulcers. After lasting some time, pannus changes into a thin, permanent layer of connective tissue.

5. *Staphyloma of the cornea* follows in some cases.

6. *Xerosis*, a contracted, dry, and scaly condition of the conjunctiva, with changes in the cornea, may occur in very severe cases.

Etiology.—Trachoma is caused by *contagion* from another eye, being transferred *through the secretion*. The danger of

contagion depends upon the amount of secretion in any given case. The transfer from one eye to another may take place by the finger, but usually by towels, handkerchiefs, and the like, which are used in common by many persons. Hence the disease spreads most extensively in schools, asylums, and barracks, and among people who live *crowded* closely together, and who are careless in regard to *cleanliness*. It is found most frequently among the *poorer classes*. It is common in Russian and Polish Jews, Hungarians, Italians, and the Irish. It occurs with especial frequency in *certain countries*—Arabia, Egypt; it is endemic in the latter country; during the Napoleonic wars the affection was carried to Europe by soldiers (hence often called *Egyptian ophthalmia*). In Europe it occurs much more extensively in the east than the west, and much more frequently in low lands (Belgium, Holland, Hungary) than in elevated countries (Switzerland). In America the negro race is comparatively free from the disease. The contagious principle in the secretion is thought to be a *micro-organism*; a number of such have been described, but so far no conclusive results have been arrived at.

Treatment consists in an attempt to reduce the inflammatory symptoms and secretion, and to check and remove hypertrophy of the conjunctiva, thus shortening the duration and diminishing the liability to conjunctival cicatrization and to sequelæ. This is accomplished either by the use of certain irritating applications, or by mechanical and surgical means.

Irritating Applications: *Sulphate of copper* in the form of a crystal or pencil is the favorite local application.

Nitrate of silver (one- or two-per-cent. solution), glycerole of *tannin* (five to twenty-five per cent.), solution of *mercuric bichloride* (1:1,000), and the *alum* stick are also employed.

Mechanical and Surgical Treatment includes expression, grattage, excision, curetting, electrolysis, *x-rays*, and galvanocautery. *Expression* is the most popular of these mechanical methods, and has the widest range of usefulness. The kind of treatment best suited for trachoma depends upon the nature of the affection, the presence or absence of inflammatory symptoms, and the stage of the disease. *Mechanical treat-*

ment is indicated in the granular and mixed forms of trachoma, with *well-marked translucent granulations*, when there is an absence of severe inflammatory symptoms; it is particularly useful in the form which Knapp calls simple or non-inflammatory. *Irritating applications* are indicated as supplementary treatment to surgical procedures, and for cases of chronic trachoma, in which the granulations are of small size, or of the papillary variety, particularly when there is considerable *thickening of the conjunctiva*.

In *acute* forms and in acute exacerbations of chronic cases, when there is *much discharge*, solution of *nitrate of silver*, one or two per cent., is applied to the conjunctiva, the excess being washed away with water or salt solution. In many cases of this sort, however, it is advisable to suspend temporarily all irritative treatment and to prescribe *cold compresses*, instillations of twenty-five-per-cent. solution of argyrol, and *mild* cleansing and *antiseptic washes*.

During the *cicatricial stage* copper is no longer indicated; the ointment of the *yellow oxide of mercury* is then of service.

If treatment is not continued until every trace of hypertrophy has disappeared, *relapses* are very common.

Sulphate of Copper.—The pencil is applied to the *everted lids* once a day, or every other day; it is drawn *lightly* across the conjunctiva two or three times, but applied only to the *hypertrophied portions*. The application should include the palpebral portion of the *transition fold* of the upper lid; in passing the copper stick under the tarsus, the cornea is protected by the lower lid (Fig. 120). The stick of copper sulphate should have

FIG. 118.—
Sulphate
of Copper
Stick.

a *flat, blunt end*, as shown in Fig. 118, and not be pointed or conical. After each application, the *excess* of copper sulphate is *washed off* with water or solution of boric acid; subsequently *iced compresses* are applied for half an hour or longer. This treatment is *continued for months*, until every trace of hypertrophy has disappeared; after a

time the applications are made more lightly and less frequently.

Expression is best performed with Knapp's roller forceps, by means of which the granulations are *squeezed out* between

FIG. 119.—Knapp's Roller Forceps for Trachoma.

two fluted rollers at the end of the shafts (Fig. 119). The operation is painful and a general anæsthetic is required. The upper lid is everted and the trachoma follicles are squeezed

FIG. 120.—Method of Applying the Sulphate of Copper Stick to the Conjunctiva of the Upper Lid.

FIG. 121.—The Operation of Expression for Trachoma, as Practised upon the Upper Lid.

out between the two extremities of the forceps. One extremity is passed back into the fornix and the other over the tarsus; using moderate compression, the forceps is drawn

forward, pressing out the contents of the granules (Fig. 121). This procedure is repeated until the lid is free from granulations and presents a dark-red surface with small red points. The lower lid is then operated upon in the same manner. After expression, the conjunctiva is often brushed vigorously with a solution of *mercuric bichloride*, 1 : 500. Care must be taken *not to cause abrasions of the cornea and not to tear the conjunctiva*. If the granulations are hard and horny, it may be well to scarify them before using the roller forceps. There are swelling and ecchymosis for a day or two after the operation, but no other evidences of reaction. *Cold compresses* and *irrigations* with solution of boric acid are indicated for several days; then any remaining roughness is treated with gentle applications of the sulphate of *copper* crystal every other day for a few weeks, or until the lids are normal.

The other mechanical or surgical means of treating trachoma are used much less frequently than expression. *Gruttage* consists in scrubbing the granulations, with or without previous scarification, with a stiff toothbrush until all the granules are removed, and then thoroughly rubbing in a solution of mercuric bichloride, 1 : 500. *Excision* consists in the removal of the fold of conjunctiva, about 10 mm. broad, containing the granules. Both of these methods cause more injury to the conjunctiva than is the case with expression. Exposure of the everted conjunctiva to the *x-ray* tube has been highly recommended.

Treatment of Complications.—Recent *pannus* is best relieved by the treatment of the conjunctiva. In addition, we may use *atropine* occasionally, so as to keep the pupil dilated and prevent posterior synechiæ, since iritis is frequently present in these cases. If the pannus is very dense, we may apply the sulphate of copper stick directly to the cornea.

In well-marked cases of pannus without corneal ulceration, and unaccompanied by much purulent conjunctival discharge, a three-per-cent. infusion of *jequirity* is sometimes rubbed into the everted conjunctiva or the powdered drug is dusted upon this surface; a very violent corneal and conjunctival inflammation is set up accompanied by the formation of a croupous

membrane (iced compresses are indicated in this stage); upon the subsidence of the process the pannus is often much improved and occasionally cured; this remedy must be used with caution, since it has been the cause of destruction of the cornea.

The operation of *peritomy*, the excision of a narrow strip of conjunctiva surrounding the cornea with a view of cutting off the vascular supply, is occasionally performed for the relief of severe cases of pannus. For active *ulceration*, *nitrate of silver* is often used, and *atropine*, if iritis is suspected.

General Treatment must not be neglected. The eye should be kept *cleansed* by the frequent use of solution of salt, boric acid, or bichloride of mercury (1:10,000). The *hygienic surroundings* of the patient should be made as perfect as possible, with proper ventilation, plenty of outdoor exercise, and good food.

Prophylaxis is very important. The patient and his family must be warned of the *contagiousness* of the secretion, and impressed with the necessity for keeping the patient's handkerchiefs, towels, wash basin, etc., apart from those of other persons. In schools, asylums, institutions, and barracks, the *prevention of epidemics* of trachoma is a very serious matter, requiring constant vigilance, careful inspection of every new addition or inmate, and the *isolation* of trachoma cases so long as the latter are capable of conveying the disease.

PHLYCTENULAR CONJUNCTIVITIS.

This disease, also known as *Pustular Conjunctivitis* and as *Scrofulous Ophthalmia*, is a *circumscribed* inflammation of the conjunctiva, accompanied by the formation of one or more small reddened projections called *phlyctenulæ*. The latter consist of accumulations of lymphoid cells, which soften at their apices, forming small *ulcers*. The phlyctenulæ may appear upon the ocular conjunctiva, and then the disease is called *phlyctenular conjunctivitis*; they may be found upon the cornea, when the affection constitutes *phlyctenular keratitis*; or they may occur, and most frequently do occur, at the *limbus*, and then we speak of *phlyctenular keratoconjunctivitis*.

or *marginal keratitis*. Very frequently they occur in all three situations in the same individual. The pathology, symptoms, and treatment being the same in all cases, it is convenient to describe the three varieties collectively under the title of *Phlyctenular Ophthalmia*.

Objective Symptoms.—The essential sign is the occurrence of one or more *small, grayish elevations*, or nodules, about the size of a millet seed, at some part of the conjunctiva or cornea, frequently at the limbus. The phlyctenule is surrounded by an area of conjunctival *hyperæmia* (Figs. 116, Plate IX, and 130, Plate X). The non-affected parts of the ocular conjunctiva are but slightly changed from the normal. The phlyctenule soon presents a small *ulceration* at its apex, which then occupies the level of the surrounding conjunctiva. It heals without leaving behind any changes in the conjunctiva. The entire process lasts from a few days to two weeks.

Generally, a number of phlyctenulæ appear at the same time; in this manner the entire ocular conjunctiva may be reddened; in such cases the palpebral conjunctiva will be congested. The nodules may become absorbed without going through the stage of ulceration.

When the phlyctenule appears upon the *cornea*, the infiltrations and subsequent ulcers are usually *superficial* and heal without the production of lasting changes in the cornea. But sometimes they spread into the corneal substance, and then leave a permanent *opacity*. Rarely, the ulcer perforates; or a number of ulcers may, by confluence, spread along the surface of the cornea.

Fascicular Keratitis.—The ulcer resulting from the phlyctenule may advance from the margin to the centre of the cornea, drawing after it a fascicle of blood-vessels. In this manner there is formed a narrow, red band of vessels, extending some distance over the cornea; at the apex of this fascicle is seen a small, gray crescent, corresponding to the advancing margin of the ulcer, which has healed in the peripheral parts. This form of ulceration always remains superficial; when the process terminates, the blood-vessels gradually disappear and a superficial linear opacity remains.

The phlyctenule may, in severe cases, involve the *deep layers* of the cornea, forming a deep infiltration; this either becomes absorbed completely or leaves an opacity of the cornea; or it may become purulent and a deep ulcer result.

There is usually considerable *lacrymation*; if there is any discharge, it is mucous or muco-purulent and not abundant. As a result of constant lacrymation, there are frequently added *blepharitis*, excoriations, and *eczema* of the lids.

Subjective Symptoms.—*Photophobia* is marked when the cornea is involved, slight or absent in conjunctival cases. When this symptom is prominent, there is considerable *blepharospasm*, and the eyes can be examined only with difficulty. There is discomfort, but not usually any pain.

Course.—The phlyctenules usually occur in *crops*; before one is completely cured another is apt to appear. In this way the course may become *protracted* and may extend over weeks. Each phlyctenule lasts from a few days to a week or two. *Relapses* are very common. Frequent recurrences may result in a number of cloudlike opacities of the cornea with superficial blood-vessels (phlyctenular pannus). Phlyctenulæ occur most frequently in *children* and in young persons, but are also seen in adults; in the latter, a single large phlyctenule may present the local appearances of episcleritis.

Etiology.—The disease is very *common*. It seems dependent upon some *constitutional error*. It occurs frequently in *children* who suffer from the tuberculous or so-called scrofulous diathesis. It is especially frequent among the *lower classes*, in whom dirt, poor food, and improper hygienic surroundings are contributory factors; also in children debilitated from disease. One frequently sees other manifestations of the predisposing diathesis, such as swelling of the cervical lymphatic glands, adenoids, *eczema*, coryza, *blepharitis*, chronic otorrhœa, etc. Sometimes, however, the affection occurs in children of the better classes apparently in good health.

Prognosis is *favorable*; serious results are rare. The phlyctenulæ usually leave no traces. In some cases corneal opacities of greater or lesser density remain, and if these are central, sight will be interfered with.

Treatment.—*Local*: Calomel dusted upon the eyeball once a day; this is believed to be slowly changed to corrosive sublimate by the action of the tears, and in this way to keep the eye bathed in an antiseptic fluid. A favorite remedy is the ointment of the yellow oxide of mercury (one or two per cent.); a piece about the size of a hempseed is deposited in the conjunctival sac and rubbed about with the lids. When there is a great deal of irritation, it is wise to withhold the yellow oxide ointment until less inflammation exists. If the symptoms of irritation are very prominent, it is better to irrigate with solution of boric acid, and to apply cold pads if the phlyctenulæ involve the conjunctiva, and hot compresses if they form upon the cornea.

If there is infiltration or ulceration of the cornea, atropine, hot compresses, and mild antiseptic washes are indicated. If there is fascicular keratitis, the ointment of the yellow oxide of mercury is employed; in such cases we can often cut short the progress of the disease by cauterizing the advancing edge of the ulcer with a fine electro-cautery point (Fig. 132), or with tincture of iodine. Bandages should not be applied; it is only in extreme cases of very deep ulceration that a bandage is indicated.

In corneal cases, the photophobia and blepharospasm are often very annoying symptoms. Instillation of solution of holocain will give temporary relief. Douching the eye with cold water, several times a day, may be effective. If a fissure of the outer canthus is present, touching this with two-per-cent. solution of silver nitrate, or the stick of copper sulphate, is of value. In extreme and persistent cases of blepharospasm, if nothing else answers, canthotomy (p. 46) may be resorted to.

General treatment is of great importance. Suitable and nourishing diet, improved hygienic surroundings, and cold sponging and bathing are useful. The nose and naso-pharynx should receive proper treatment. These patients should not be allowed to remain in the house and in the dark, as they are inclined to do on account of the photophobia. Smoked glasses are prescribed to relieve this symptom. Calomel (gr. $\frac{1}{2}$ t.i.d.),

iron (syrup of the iodide), quinine, and arsenic are useful for internal administration, and *cod-liver oil* is of great benefit.

SPRING CATARRH.

A rather uncommon disease of the conjunctiva, of *chronic* course, lasting for years, continuing *during warm weather* and disappearing entirely or to a considerable extent with the beginning of winter. It is also known as *Vernal Catarrh*. The disease occurs chiefly in *children*, most frequently in boys. It may attack the tarsal or the bulbar conjunctiva, or both.

Objective Symptoms.—The *tarsal conjunctiva* presents flattened *papillæ* covered by a delicate, bluish-white *film*. The *bulbar conjunctiva* presents at the inner and outer portions of the limbus hard, gelatinous *hypertrophies*, which may extend into the cornea for a short distance, and which sometimes surround it. During the winter these changes become less marked or disappear; they return with the advent of warm weather.

Subjective Symptoms include a feeling of *heat*, *lacrymation*, *itching*, and *photophobia*; these become worse in warm weather and disappear in the winter.

Course.—The disease usually attacks *both eyes* and lasts in this intermittent way for several years or longer, finally becoming extinct and leaving no traces behind. Its *etiology* is *unknown*. It may be associated with *hay fever*.

Treatment.—There is no known cure. The subjective symptoms can be made less annoying by the remedies in use for catarrhal conjunctivitis. The agents most frequently used are *boric acid*, *corrosive sublimate* (1:5,000), and white precipitate ointment; acetic acid (one drop of the dilute acid to half an ounce of water) and salicylic acid ointment (one-per-cent.) have also been advocated. The greatest relief follows the instillation of one-per-cent. solution of *holocain* in 1:10,000 *adrenalin*, the use of *cold compresses*, and the wearing of *smoked glasses*. If the hypertrophies are of considerable size, they may be removed. When the granulations are large, sulphate of copper or expression may be of service.

SYMBLEPHARON.

A *cicatricial attachment* between the conjunctiva of the *lid* and the *eyeball* (Fig. 122). It may affect both lids, but usually the *lower*; sometimes it includes part of the cornea. It is called *anterior* or *partial*, when extending bridge-like

FIG. 122.—Symblepharon.

from lid to globe, leaving a free portion of conjunctiva corresponding to the fornix; *posterior*, when it involves only the fornix; and *complete* when it affects all the conjunctiva.

Etiology.—It is caused by the junction of two opposing granulating surfaces; hence, it occurs after *injuries*, especially *burns* from lime, acids, and molten metal; sometimes it follows

trachoma, and occasionally diphtheritic conjunctivitis.

Symptoms.—Symblepharon often *interferes* with the *movements of the eyeball*, and this may cause diplopia. Traction upon the adherent parts excites *irritation*. In severe cases the cornea is included and sight interfered with; or, if there is inability to close the lids, lagophthalmos and its sequelæ may be present.

Treatment.—If *anterior and not extensive*, we divide the band and keep the two raw surfaces from uniting by *separating* them daily with a probe until they have cicatrized separately; the interposition of a small roll of absorbent cotton saturated with some bland oil or ointment may aid in this purpose. Or the band may be ligated and the ligature allowed to slough through.

In *more severe forms*, and in all cases of posterior and complete symblepharon, the separated raw surfaces must be cov-

ered with conjunctiva or with *grafts* of skin or mucous membrane to keep them from uniting. This may be done (1) by *loosening* the adjacent bulbar conjunctiva and sewing it over the defect, (2) by *transplanting* pieces of mucous membrane from the lip or from the rabbit's conjunctiva, (3) by *skin flaps* passed from adjacent surfaces, and (4) by *Thiersch skin grafts*, taken from other parts of the body and supported on an artificial eye or piece of sheet lead until adhesion has taken place; the last method is usually successful.

PTERYGIUM.

A *triangular fold of membrane*, extending from the inner or outer part of the ocular conjunctiva to the cornea (Fig. 123); the apex is immovably united to the cornea, the base spreads out and merges with the conjunctiva.

Symptoms.—When recent, pterygium is rich in blood-vessels and hence of a red color; later it changes into a white, *tendinous membrane*. It *grows slowly* toward the centre of the cornea, giving rise to moderate symptoms of conjunctival *irritation*, and it may eventually cover a considerable part of the cornea; finally it becomes *stationary*. Besides more or less irritation, it causes *disfigurement*, and it spreads over the cornea *interfering with vision*. It is generally situated to the *inner* side of the cornea, less frequently to the outer side or in both situations. It may occur in one or both eyes.

FIG. 123.—Pterygium.

Etiology.—Pterygium is thought by some to originate from pinguecula, the process extending to the cornea and drawing the conjunctiva after it. It occurs in *elderly* persons who are exposed to *wind* or *dust* (farmers, coachmen, masons, sailors). It is uncommon among the better classes.

Treatment consists in *removal* by one of a number of different *operative* methods. The pterygium may be *dissected away*

with a sharp scalpel, or Beer's knife (Fig. 53), and *cut off*, the conjunctival defect being closed by uniting the upper and lower borders, undermining the conjunctiva if necessary to bring the edges together. The *apex* of the pterygium must be thoroughly excised from the cornea, and its attachment in this situation scraped or *cauterized* with the electro-cautery, to prevent recurrence. Instead of cutting off the pterygium it may be dissected up and *stitched underneath* the detached conjunctiva, either above or below; or it may be divided into halves, of which one is *transplanted* above and the other below, being held in the conjunctival pocket by a stitch.

INJURIES OF THE CONJUNCTIVA.

These are very common, and include:

1. *Foreign bodies in the conjunctival sac*, consisting of dust, iron, coal, or ashes. They usually adhere to the inner surface of the *upper lid*, causing severe pain and irritation, and are readily removed after eversion of the lid.

2. *Wounds*.—Extensive wounds of the conjunctiva should be closed with a stitch.

3. *Burns* are quite common, being due to boiling water, steam, lime, mortar, molten metal, and acids. Following the accident a grayish *eschar* forms; this separates and leaves a *granulating* surface, which heals by *cicatrization*; in this way *symblepharon* often results.

The treatment consists in the complete *removal* of the caustic substance as soon as possible. Solid particles are removed with absorbent cotton or forceps. Then the conjunctival sac is *washed out* with solutions which tend to *neutralize* the corrosive substance or render it insoluble. In the case of lime, mortar, or caustic alkalis, we flush out with a stream of solution of boric acid; or we may wash out the eye with oil. If the corrosive agent consisted of an acid, the eye is irrigated with a weak solution of sodium bicarbonate. Subsequently we use *cold* compresses, *atropine*, and sometimes a bandage. After the loosening of the eschars, we must *separate the adhesions* frequently. *Symblepharon* often occurs notwithstanding the greatest care.

CHAPTER VIII.

DISEASES OF THE CORNEA.

Anatomy.—The cornea is the clear, transparent, anterior portion of the external coat of the eyeball; it is nearly circular, but is slightly wider in the transverse than in the vertical direction; its radius of curvature is somewhat shorter than that of the sclerotic; the junction of the two is known as the *limbus*, but their tissues are in complete continuity. The cornea is composed of five layers (Fig. 124), from without inward: (1) Layer of epithelial cells; (2) Bowman's membrane; (3) the proper substance of the cornea; (4) Descemet's membrane; and (5) a layer of endothelium.

The *epithelium* covering the front of the cornea is of the stratified variety, formed of flattened, scaly epithelial cells superficially, of polygonal cells beneath these, and of columnar cells most deeply. Practically it is part of the bulbar conjunctiva.

Bowman's membrane is a thin, homogeneous membrane which separates the corneal epithelium from the proper substance of the cornea. Although usually described as a separate membrane, it is really a part of the corneal substance, and when highly magnified is seen to be composed of fine fibres which are intimately connected with the subjacent layer.

The *proper substance of the cornea*, the thickest layer, is formed of connective tissue arranged in *lamellæ*, the planes of which are parallel to the surface of the cornea; these are connected with one another and cross at right angles in alternating layers. The ultimate fibrils of which the lamellæ are composed, as well as the

FIG. 124. — Vertical Section of the Cornea, Showing Minute Anatomy. A, Layer of epithelial cells; B, Bowman's membrane; C, Proper substance of the cornea; D, Descemet's membrane; E, layer of endothelium.

different bundles of fibrils forming the lamellæ, are held together by means of a transparent *cement* substance. The corneal substance is traversed by a system of spaces or *lacunæ*, situated in the cement substance separating the laminae, and sending off prolongations in every direction; these form small *canals* by means of which the lacunæ of the same plane and those placed above and below communicate. The spaces are partly filled with branching cells (*corneal corpuscles*), the branches of the cells passing into the small canals and communicating with adjoining cells. The cells do not completely fill the lacunæ, but leave room for the passage of *lymph* and lymph corpuscles. The proper substance of the cornea passes uninterruptedly into the sclera.

Descemet's membrane (the posterior elastic lamina) is a thin, firm, structureless, transparent, and highly *elastic* layer, placed posterior to

the proper substance of the cornea; at the periphery of the cornea it passes over into radiating bundles of elastic fibres which form the *ligamentum pectinatum*.

Posteriorly, next to the anterior chamber, is a single layer of flattened, hexagonal cells, the *endothelium*.

The cornea is not provided with blood-vessels. The *capillary loops* from the anterior ciliary vessels form a ring around the circumference of the cornea. Its nutrition is provided for by the system of lymph canals just

FIG. 125.—Arcus Senilis.

described. It is richly supplied with *nerves* derived from the ciliary nerves.

The line between cornea and sclera is known as the *limbus*. Near the margin of the cornea, just within the sclerocorneal junction, we frequently find an opaque, whitish ring or part of a ring; this is known as the *arcus senilis* (Fig. 125); it is due to a deposit of fatty granules, and most frequently occurs in advanced age, though occasionally it is found in younger persons.

Inflammations of the Cornea (Keratitis)

eral present the following symptoms:

Objective Symptoms.—(1) *Infiltration*, with dulness of face and diminution of transparency; this may be followed by (a) *complete absorption* of the infiltration, (b) *incomplete absorption*, leaving opacities, and (c) *suppuration*, with formation of pus.

tion of an *ulcer*. (2) Limited or general *vascularization*, the blood-vessels being derived from the conjunctival loops at the limbus. (3) *Circumcorneal injection*. (4) There is often a complicating *conjunctivitis*. (5) Neighboring deep parts are frequently involved (*iris* and *ciliary body*), as a result of which there may be pus in the anterior chamber (*hypopyon*).

Subjective Symptoms.—*Pain, photophobia, blepharospasm, lacrymation, and interference with vision.*

Varieties.—Keratitis may be divided into suppurative and non-suppurative.

Suppurative Keratitis.—The common forms are (1) phlyctenular keratitis, and (2) ulcers of the cornea. The uncommon forms are (3) keratitis from imperfect closure of the eyelids (*lagophthalmos*), (4) neuroparalytic keratitis, and (5) xerotic keratitis.

Non-Suppurative Keratitis.—The common forms are (1) interstitial keratitis, and (2) vasculo-nebulous keratitis (*pannus*). The uncommon forms are (3) vesicular keratitis, (4) superficial punctate keratitis, (5) keratitis profunda, (6) sclerosing keratitis, and (7) ribbon-shaped keratitis.

Phlyctenular Keratitis has been described under the title Phlyctenular Conjunctivitis (p. 103), and the special symptoms arising when the cornea is involved have been pointed out.

ULCER OF THE CORNEA.

An *infiltration*, followed by suppuration and *loss of substance* of the cornea. The affection is of common occurrence.

Subjective Symptoms.—*Pain, photophobia, lacrymation, and blepharospasm.* Sometimes all these symptoms are slight, or even absent, and yet the ulcer may be a very extensive and

which one.
the *subjective Symptoms.*—An ulcer begins with a dull, grayish, yellowish-yellow *infiltration* of a circumscribed portion of the cornea (Figs. 126 and 127, Plate X); *suppuration* takes place in this area, the superficial layers are cast off, and thus there is a *loss of substance*. The process may progress in two directions: it may either travel over the cornea so as to involve a

greater *area*, or it may become *deeper*; it may extend both in area and in depth. Very often the advance takes place in one direction, across the cornea; sometimes there is at the same time a tendency to heal at the opposite side, so that the ulcer merely changes its situation (creeping or serpiginous ulcer). There is nearly always more or less grayish *infiltration* of the cornea immediately *surrounding* the loss of substance, and considerable ciliary *injection*.

If the ulcer is small and superficial, it will cleanse itself in the course of a few days. The destroyed portion of the cornea will be cast off, the infiltrated border will become clear, and repair set in; this is accompanied by the appearance of blood-vessels which spring from the limbus; the process terminates in cicatrization. When the ulcer is very superficial, the cornea may remain perfectly transparent. But when some of the proper substance of the cornea has been destroyed, new connective tissue takes its place, and such a scar is always more or less *opaque*. The seat of the ulcer may also be marked by a slight depression (*corneal facet*).

The detection of the extent of infiltration and ulceration is facilitated by the instillation of a few drops of a two-per-cent. solution of *fluorescein*, which stains green all such ulcerated or infiltrated parts.

When the ulcer is deeper, both subjective and objective symptoms are more pronounced, and the complications and sequelæ are more serious. Neighboring structures give evidences of inflammation: *conjunctivitis*, congestion of the iris, even *iritis* with its symptoms, including hypopyon. *Hypopyon* is a collection of pus in the anterior chamber. The pus is not derived from the ulcer, but is an exudation from the inflamed iris and ciliary body. It collects at the bottom of the anterior chamber (Fig. 127, Plate X), or it may partially or completely fill this space. It may either remain fluid, or when mixed with fibrin it may form a semi-solid, globular mass. Such an ulcer may heal with no other permanent injury except marked corneal *opacity*, or there may be bulging (*anterior staphyloma*). But deep and spreading ulcers frequently have their course modified by the occurrence of *per-*

FIG. 131.—Interstitial Keratitis.

foration of the cornea, which, in healing, affects the usefulness and safety of the eye in various ways.

Perforation of the Cornea is often preceded by a *protrusion of Descemet's membrane* through the floor of the ulcer, forming a small, transparent vesicle. Perforation may be spontaneous, or it may be caused by increased pressure resulting from the blepharospasm, various straining efforts, such as crying, sneezing or coughing, or occasionally by force exerted in examining the eye. The aqueous humor escapes, often carrying the iris into the wound; the eye feels soft; the anterior chamber is obliterated, and iris and lens are in apposition with the cornea. Perforation of the cornea has a favorable effect upon the course of the affection: the subjective symptoms are relieved and the ulcer begins to heal as a result of diminished tension.

When the opening closes by cicatrization, the iris may regain its normal position. But frequently it continues *adherent* to the walls of the perforation, or remains *prolapsed*, and becomes incorporated with the scar. Such a condition is called *anterior synechia*; and since the cicatrix forms a dense, white opacity of the cornea, it is known as *adherent leucoma* (Fig. 128, Plate X). Most frequently only a portion of the iris is drawn into the scar; the pupil is then more or less pear-shaped. Occasionally the entire pupillary margin may be adherent, causing both exclusion and occlusion of the pupil.

At the time of perforation, the *lens* may become dislocated, and occasionally it escapes. When it is pushed forward and lies in apposition with the margins of the opening and then recedes after the anterior chamber is re-established, it frequently presents a proliferation of the subcapsular epithelium which has become irritated by the pressure of the lens upon the cornea, forming a white spot upon its anterior surface (Fig. 214), known as anterior capsular or *anterior polar cataract*.

Occasionally the perforation fails to close and a *fistula* of the cornea results; this condition exposes the eye to subsequent serious inflammation and jeopardizes its safety. *Iridocyclitis* and even *panophthalmitis* may follow perforation, especially if the suppurative process be a virulent one.

Etiology.—Ulcers of the cornea are usually found in *adult and aged* individuals; phlyctenular ulcers are the only ones which are common in children. Ulcers are much more frequent among the *lower* than among the better classes, and occur often in individuals in whom the *general health is poor*.

The process is essentially an *infection* by various micro-organisms (pneumococci, streptococci, staphylococci, Plate VIII), frequently introduced by the secretion of chronic *conjunctivitis*, and especially by that of *dacryocystitis*.

The exciting causes are: (1) traumatism (foreign bodies, injuries); this is one of the most frequent causes; (2) conjunctival inflammations (gonorrhœal ophthalmia, ophthalmia neonatorum, trachoma, diphtheritic conjunctivitis); (3) phlyctenular keratitis; (4) disturbances in the nutrition of the cornea (paralysis of trigeminus, keratomalacia, glaucoma); (5) infection during operations; (6) variola; (7) herpes.

Clinical Forms.—Certain variations in the course of corneal ulcers have already been considered. The nomenclature of ulcers of the cornea is quite extensive and is founded upon peculiarities in the symptoms or course. The following warrant special mention:

(1) *Simple Ulcer* is the name often given to a small and superficial ulcer, with symptoms of slight or severe irritation, no tendency to perforation, terminating in uncomplicated healing; phlyctenulæ and slight injuries often cause such ulcers.

(2) *Deep Ulcer* is one which shows a tendency to involve the deeper layers and to perforate rather than to spread over the cornea. The symptoms are apt to be marked, the iris is usually involved, and hypopyon is often present; hence the results are often serious.

(3) *Serpent Ulcer* (Creeping or Spreading Ulcer, Infected Ulcer, Hypopyon Keratitis) is a very *virulent* form, in which the process tends to *spread* over a considerable portion of the cornea and at the same time extends into its *depth*. The subjective symptoms are usually severe, though occasionally they are slight. The process begins as a grayish-yellow infiltration near the centre of the cornea, rapidly changing to an ulcer with sloughing margins, especially at the advancing side

where there is frequently a yellowish crescent (Fig. 127, Plate X). The rest of the cornea is often dull, gray, and infiltrated. The process advances very *rapidly*, much of the cornea becomes destroyed, and *perforation* takes place. There is early and intense *iritis*, and *hypopyon* is almost always present. Owing to the virulence of the ulcer and the accompanying *iritis*, much *damage* results to the eye. Adhesion and prolapse of the iris are frequent, the pupil is often occluded, and iridocyclitis and panophthalmitis are not uncommon. Considerable opacity of the cornea always ensues, and often staphyloma. There is, therefore, considerable *impairment of vision*, which not infrequently is reduced to perception of light.

(4) *Rodent Ulcer* is a rare form, of slow course, in which the ulceration always remains superficial, but most of the cornea becomes involved, and thus the resulting opacity and interference with vision are pronounced. It commences at the periphery and extends toward the centre of the cornea, being intermittent in its progress.

(5) *Marginal Ring Ulcer* is rare, of slow and intermittent course, successively involving different parts of the margin, so that it tends to extend all around the cornea.

(6) *Transparent Ulcer* is small, superficial, central, shows no tendency to spread or to perforate, occurs chiefly in children, and is followed by little or no opacity, but often by a small pit (facet).

(7) *Herpetic Ulcer* results from a ruptured herpetic vesicle, and spreads superficially, involving more or less of the surface of the cornea.

(8) *Dendriform Ulcer* (Dendriform Keratitis) is an infrequent and chronic form of superficial ulcer, which commences with a grayish line and spreads by sending out branches which present small knob-like extremities.

(9) *Catarrhal Ulcer* is crescentic, marginal, and complicates catarrhal conjunctivitis.

(10) *Abscess of the Cornea* is a purulent infiltration in the substance of the cornea, covered both superficially and posteriorly by sound tissue. The subjective symptoms are those of serpent ulcer; it is usually accompanied by *iritis* and *hypopyon*.

Occasionally, when deeply situated, the pus may become absorbed; generally, however, the superficial layers burst and an ulcer results.

Onyx is an obsolete term, which refers to the settling of pus between the layers of the cornea, the occurrence of which is now believed to be extremely doubtful.

Treatment may be divided into (1) constitutional, (2) treatment of pre-existing local conditions, (3) local treatment of the ulcerative process.

Constitutional.—Since ulcers usually occur in persons in whom the general condition is below par, it is necessary to *improve the tone of the system* by attention to diet, fresh air, hygienic surroundings, condition of the bowels, etc., and often to administer tonics.

Treatment of Pre-existing Local Conditions.—Foreign bodies are to be removed and other local irritating conditions remedied. The various forms of conjunctivitis and dacryocystitis must receive careful attention.

Local Treatment includes atropine (sometimes eserine), bandage, hot compresses, antiseptic lotions, scraping, cauterization, paracentesis of the cornea, and division of the ulcer by Saemisch's method.

Atropine must be instilled in sufficient quantity to keep the pupil dilated; it has a sedative effect upon the cornea, paralyzes the ciliary muscle and iris, and acts favorably upon the ulcer by diminishing the iritis. One drop of a one-per-cent. solution may be used three times a day or oftener. When the ulcer is central, the iris is drawn away from the seat of perforation, and there is less danger of adhesion or prolapse. When the ulcer is *peripheral* and deep, so that a perforation is imminent, *eserine* (one-third of one per cent.) may be substituted, for the same reasons.

Protection is afforded by *smoked glasses* or by a *bandage*. When there is much discharge, the bandage is contraindicated in superficial ulcers. But in any case in which perforation of the cornea is liable to occur, a firm (*pressure*) bandage is applied; this must be removed and replaced several times a day to permit cleansing of the eye and local applications.

Hot Compresses should be applied for half an hour at a time, several times a day; they favor healing of the ulcer.

Antiseptic Lotions such as solutions of boric acid, sodium chloride, bichloride of mercury (1:6,000), act as cleansing agents, and are especially useful when there is much discharge.

Other Measures are sometimes resorted to: *Iodoform* sprinkled upon the cornea or applied in the form of an ointment, subconjunctival injections of corrosive sublimate (1:5,000), *argyrol* or protargol (twenty-five per cent.), formalin (1:2,000).

To Limit Spreading: If these remedies are insufficient and the ulcer spreads, we must destroy the infective focus either by *scraping* the floor and margins of the ulcer with a small, sharp spoon or curette or, better, by *cauterizing* this area. Cauterization is effected by tincture of iodine, pure liquid carbolic acid applied with a finely pointed brush, the stick of nitrate of silver, and by the actual cautery or the electro-cautery.

Tincture of Iodine offers a very efficient mode of disinfecting and cauterizing corneal ulcers. A piece of absorbent cotton is wound firmly upon an applicator, dipped into tincture of iodine and then exposed to the air for a few seconds so that there is no excess of liquid. It is now brushed upon the ulcer and its infiltrated margins. It is usually necessary to repeat the cauterization a number of times on successive days.

Electro-Cautery.—After thorough anæsthesia of the eye, one of the electrodes shown in Fig. 132 is placed cold upon the part to be cauterized, the connection made so that the burner assumes a deep red color, and then the connection quickly broken. Successive points (especially the margins of the ulcer) are cauterized in this manner, each for a very short period, so as to prevent perforation and the propagation of heat to deeper parts. In the absence of an electro-cautery apparatus, a platinum probe fitted in a wooden handle or even a squint hook may be heated in the flame of an alcohol lamp,

FIG. 132.—Eye Electrodes.

and used for this purpose. It may be advisable to render the outlines of the ulcer more distinct by the preliminary instillation of a drop of fluorescein solution (p. 114).

Paracentesis of the Cornea is another valuable measure. This puncture is frequently made with a paracentesis trocar, which

FIG. 133.—Paracentesis Trocar.

is provided with a thick shoulder to prevent the instrument from penetrating too far (Fig. 133); it may be made with the lance-shaped knife (Fig. 183), or with the Graefe cataract knife (Fig. 185). After local anæsthesia and fixation of the eyeball with the fixation forceps, the instrument is passed perpendicularly through the cornea, near its lower margin, unless the situation of the ulcer requires another site. As soon as its point reaches the anterior chamber, the handle of the instrument is depressed and the knife or trocar is pushed on horizontally, avoiding injury to the iris or lens, until the incision is about 3 mm.

long. Then it is withdrawn slowly with pressure upon the posterior lip of the wound, so as to evacuate the contents of the aqueous chamber gradually. It may be necessary to repeat the paracentesis or to reopen the wound with a probe daily until the ulcer cleanses itself.

Saemisch's Operation of splitting open the ulcer has been almost entirely abandoned in favor of paracentesis and the electro-cautery, but is useful in some severe forms of serpent ulcers. A Graefe knife is thrust through clear corneal tissue 1 or 2 mm. to the outer side of the ulcer, made to traverse the anterior chamber, and brought out 1 to 2 mm. to the inner side of the ulcer. The edge of the knife is directed forward and the ulcer is split through its centre and the hypopyon removed. The incision must be reopened with a probe daily, until the ulcer becomes clean.

After spontaneous perforation of an ulcer, atropine is instilled, a pressure bandage applied, and perfect rest insisted upon. If there is a recent *prolapse* of the iris, the latter is freed from adhesion to the margins of the opening and then *excised*; this has the effect of an iridectomy. But if the pro-

lapse has existed for some days it must be allowed to remain; subsequent operative interference may then be indicated.

After the healing process has become fairly initiated, certain mildly stimulating remedies, such as the ointment of the yellow oxide of mercury, are used to hasten cicatrization and to clear up the cornea as much as possible.

Keratitis from Defective Closure of the Lids.—This form of keratitis is due to *exposure of the cornea* when it remains uncovered by the lids (*lagophthalmos*). Under such circumstances the cornea becomes desiccated, the conjunctival secretion and atmospheric dust settle upon it, infiltration and ulceration take place, with the subsequent course of ulcer of the cornea. The causes are paralysis of the orbicularis (*facial paralysis*), marked exophthalmos, and various deformities of the lids. *Treatment* consists in relieving the lagophthalmos if possible, frequent irrigation of the conjunctival sac with cleansing solutions, and closure of the lids by bandage or plaster. Unless the process has gone beyond certain limits it can be controlled by this plan of treatment.

Neuroparalytic Keratitis is a form of infiltration and ulceration of the cornea observed after paralysis of the *trigeminus*. The changes are considered by some to be trophic, by others to be due to exposure and lodgment of foreign substances upon the insensitive cornea. There is no pain or lacrymation, the course is chronic, and the result is considerable opacity of the cornea. *Treatment* consists in applying a bandage to the eye, or keeping the lids closed with plaster or suture; atropine and hot compresses may be of service.

Xerotic Keratitis (*Keratomalacia*) is the result of lack of nutrition of the cornea. It is an uncommon disease which occurs in greatly debilitated children. The cornea corresponding to the palpebral aperture becomes cloudy, desiccated, covered with scales, and ulcerates and perforates. The great majority of such patients die from the disease which is responsible for the corneal condition. *Treatment* consists in measures to increase the general strength; locally, hot compresses, antiseptic lotions, bandaging, and atropine are indicated.

INTERSTITIAL OR PARENCHYMATOUS KERATITIS.

A *cellular infiltration* of the middle and posterior layers of the cornea, of frequent occurrence in *childhood*, *chronic* in its course, not leading to ulceration, but accompanied by more or less *inflammation of the uveal tract*.

Objective Symptoms.—The affection begins either in the centre or at the margin of the cornea. If it starts in the centre, this part will present a *grayish infiltration*, the superficial layers at first retaining their normal lustre; this central patch soon spreads so that the whole cornea becomes implicated. If it commences at the periphery, one or more grayish crescents are seen, which soon spread toward the centre and involve all the cornea. After the infiltration has become general, the cornea will become *softened*, of a dense grayish or sometimes yellowish-gray color, so that the iris can no longer be seen, and vision is reduced to little more than perception of light. The surface of the cornea is now *steamy* and resembles ground glass. At this period or even before, deep-seated blood-vessels (derived from the anterior ciliary) make their appearance and pervade more or less of the cornea (Fig. 131, Plate X); they cover either the periphery, circumscribed sectors, or the whole cornea. This *vascularization* gives rise to a dirty-red or yellowish-red discoloration, which is known as the *salmon-colored patch*. The progress thus far is accompanied by *irritative symptoms* and lasts one or two months.

The inflammation then begins to subside. The periphery of the cornea *clears up*, the blood-vessels become fewer, the irritative symptoms disappear, and *vision improves*. Several months or even a longer period is consumed in this process, the centre of the cornea being the last portion to clear. In favorable cases, after a year or more, nothing but a very faint, central opacity and evidences of a few minute peripheral vessels can be found.

Not all cases will, however, run such a benign course. *The anterior portion of the uveal tract is regularly involved*. In mild cases, this will consist merely in congestion of the iris.

But in *more pronounced types* there will be *iritis, choroiditis, cyclitis*, and changes in the *vitreous*; in such cases, after the cornea has become less opaque, we may find evidences of these inflammations, in the form of adhesions of the iris to the lens (posterior synechiæ), changes in the iris and choroid, opacities of the vitreous, and even exclusion of the pupil and iridocyclitis. Staphyloma of the cornea may also follow. So that more or less serious *impairment of sight* may ensue as a result of these inflammatory processes. Furthermore, the clearing-up process in the cornea may come to a standstill, leaving a dense *opacity* which also causes loss of useful vision.

Subjective Symptoms.—During the period of infiltration and vascularization there

will be *photophobia, lacrymation, pain*, and *interference with vision*, the intensity usually depending upon the severity of the process; these symptoms gradually subside during the progress of absorption.

Both eyes are usually involved; frequently the inflammation in the second eye commences after that in the first has existed for some weeks or months.

Etiology.—The disease usually occurs *between the fifth and fifteenth years*, less commonly after this period, and rarely after thirty. The great majority of cases are due to *inherited syphilis*; in few instances it depends upon acquired syphilis,

FIG. 134.—From a Photograph of a Patient, the Subject of Interstitial Keratitis, exhibiting the Signs of Inherited Syphilis, including Hutchinsonian Teeth.

tuberculosis, or occurs without known cause. In many cases there will be other

Signs of Inherited Syphilis (Fig. 134), such as characteristic physiognomy, peculiar conformation of the skull (square forehead, prominent frontal eminences, depressed bridge of nose), radiating scars at angles of mouth, scars in the mouth and pharynx, ozæna, enlarged cervical lymphatic glands, nodes on the bones, and more or less impairment of hearing. The permanent teeth are ill-developed, their angles rounded off, and there is often a crescentic notch in the free margin; these changes are especially marked in the upper central incisor teeth (*Hutchinsonian teeth*, Fig. 134).

Treatment.—*Local*: *Atropine*, protection from light by *smoked coquilles* or by a shade, *hot compresses*. When the cornea begins to clear, we employ mild *stimulating ointments*, such as yellow oxide of mercury and calomel, often combined with gentle *massage*, or instil dionin in two to five per cent. solution. We must be careful not to apply stimulating treatment too early.

Constitutional: *Calomel*, gr. $\frac{1}{16}$ four times a day, or *potassic iodide*, gr. v., combined with *corrosive sublimate*, gr. $\frac{1}{40}$, t.i.d. Syrup of the *iodide of iron* or other preparation of iodine, cod-liver oil, iron and quinine, and attention to the general health. In the uncommon cases occurring in adults, we prescribe iodide of potassium, with or without mercury.

Pannus (*Vasculo-nebulous* or *Vascular Keratitis*) has been described in connection with trachoma (p. 97).

UNCOMMON FORMS OF NON-SUPPURATIVE KERATITIS.

Vesicular Keratitis comprises a number of inflammations of the cornea, in which the distinguishing feature is the occurrence of groups of small clear *vesicles*, or of a single large transparent *blister*, with marked *irritative symptoms*. Vesicles occur in *herpetic keratitis* (herpes corneæ) and in the keratitis accompanying *zoster* corresponding to the distribution of the fifth nerve, bullæ in *keratitis bullosa*.

Superficial Punctate Keratitis complicates acute affections of the respiratory tract and begins with the symptoms of acute conjunctivitis. Numerous small gray spots appear in the superficial layers of the cornea, beneath Bowman's membrane; these are accompanied by gray radiating lines and by some general clouding. The disease resembles herpes, but there are no vesicles, no ulceration, and deeper parts are not involved. It occurs in young persons, is usually bilateral, and lasts several months, after which there is complete absorption. Treatment comprises attention to the conjunctivitis and the bronchial affection, the use of atropine, hot compresses, and smoked glasses, and later the ointment of the yellow oxide of mercury.

Keratitis Profunda is a form of deep-seated inflammation of the cornea occurring in adults, in which a gray, central opacity of the cornea develops, accompanied by irritative symptoms; it becomes entirely or almost perfectly absorbed in a few weeks, and requires treatment similar to that of interstitial keratitis.

Sclerosing Keratitis is the name given to the corneal complication of scleritis (p. 135). The portion of the cornea adjacent to the scleritic nodule participates in the process, and a triangular opacity remains. The symptoms and treatment correspond to those of scleritis.

Ribbon-shaped Keratitis (*Transverse Calcareous Film of the Cornea*) is a whitish or grayish band, which extends across the cornea opposite the palpebral aperture, and often contains lime. It occurs usually in old persons, and in eyes which have been seriously injured or lost by a previous intraocular affection. Treatment consists in gently scraping away the band and using solutions of sodium carbonate (gr. i. to $\frac{3}{4}$ i.).

A number of other forms of keratitis are described, but are of rare occurrence.

Punctate Keratitis (*Descemetitis*) is the name given to dot-like deposits upon the posterior surface of the cornea which we now know to be part of the exudation in inflammations of the uveal tract (iritis, cyclitis, iridocyclitis).

This condition is never the result of an inflammation limited to the cornea. It usually shows upon the lower portion of Descemet's membrane, the area being triangular with the base at the margin and the apex near the centre of the cornea (Fig. 152, Plate XI). These deposits are usually absorbed.

BULGING OF THE CORNEA.

This condition is either of inflammatory origin, when it is known as *staphyloma*, or of non-inflammatory origin, when it is called *keratoconus*.

Staphyloma of the Cornea is a *protrusion* of a previously inflamed cornea (Fig. 135), formed of more or less corneal tissue, iris, and cicatrix; very often the iris forms the chief part. It develops after corneal softening, ulceration, and perforation. It may be *total*, when it occupies the situation of the entire cornea, or *partial*, when it occupies only a portion of this area. It may be globular, conical, or lobulated. It is *whitish* with bluish areas represent-

FIG. 135.—Staphyloma of the Cornea.

ing spots where pigment shows through the thin cicatrix; it may be all white or all bluish. Some blood-vessels are frequently seen on the surface. It varies in size, being small in some cases and so large in others that the lids cannot close.

Symptoms.—Besides the objective signs just mentioned, there are changes in the eyeball, in the staphyloma, and in the lids. There is almost always *increased tension*, often due to obliteration of the pupil. This condition causes *pain*, produces *changes in the interior* of the eye (atrophy of the optic nerve, retina, and choroid) which lead to *blindness*, results in an increase in the size of the bulging, and is responsible for staphyloma of the sclera. The conjunctiva becomes the seat of inflammation from mechanical irritation. The summit of

the protrusion becomes dry and ulcerated, and there is frequently rupture followed by closure of the opening; this process may be repeated a number of times, until the eye is lost and a *shrunk globe* remains.

Even before these secondary changes have taken place, there is considerable *deformity*, and *sight* is very much *reduced*. In total staphyloma there will be merely perception of light; in the partial form the amount of sight will depend upon the condition of the cornea which is preserved, the position of the pupil, and the extent to which the curvature of the cornea has become altered.

Treatment.—In *partial staphyloma*, an *iridectomy* should be performed (p. 177) for the purpose of reducing tension, flattening the protrusion and preventing its increase, and to serve for optical purposes. We select the part of the iris corresponding to the most clear portion of the cornea. If there is no anterior chamber and the iris lies against the posterior surface of the cornea, this operation is impossible. In such cases, we may *incise*, or *excise* a portion and unite with sutures, followed by a pressure *bandage* for a considerable period of time.

In *total staphyloma*, we resort to incision, abscission, or enucleation. *Incision* is followed by the extraction of the lens if it still be present. *Abscission* is performed by cutting through one-half of the protrusion with the knife, and separating the other half from the ring of corneal tissue forming its base with forceps and scissors; the lens is removed; the edges of the corneal gap are then brought together with sutures drawn through the corneal tissue, or better, through the conjunctiva which has previously been freed around the limbus. *Enucleation*, or one of its substitutes, is practised in certain cases in which the staphyloma is very large, or in which for various reasons abscission is not advisable.

Keratoconus or Conical Cornea.—A non-inflammatory *conical protrusion* of the centre of the cornea (Fig. 136), due to a gradual *atrophic thinning*, in consequence of which the cornea is unable to resist the normal intraocular pressure. The condition is of rather *infrequent* occurrence

and is usually observed in *young women*. It is easily seen when well marked; when less developed, it is recognized by the annular shadow produced when the eye is examined with the ophthalmoscope at a distance, by the *alteration* in shape of the image when *Placido's disc* (Fig. 6) is used, and by *distortion* of the picture of the fundus as seen with the *ophthalmoscope*.

FIG. 136.—Keratoconus.

The condition tends to *progress* for many years before it comes to a standstill. When pronounced, it often presents a slight opacity at its apex; it never ulcerates. Conical cornea causes *myopia* and *astigmatism* and seriously *interferes with sight*, especially peripheral vision, even after the best possible correction with glasses. *Treatment* consists in providing concave *spherocylinders*, repeated paracentesis followed by the long-continued application of a pressure bandage, pilocarpine or eserine to diminish tension, and abscission or *cauterization of the apex* of the cone to cause flattening by subsequent cicatrization.

Cauterization is used most frequently and is the most successful; it is generally followed by an iridectomy, for the purpose of bringing the pupil opposite clear cornea. The electrode used for this operation (Fig. 137) has a spherical tip with which the apex of the cone is cauterized as deeply as Descemet's membrane, or even with perforation.

FIG. 137.—Corneal Electrode for Keratoconus.

OPACITIES OF THE CORNEA.

This term refers to a lack of transparency of the cornea resulting from inflammation, ulceration, or injury. According to density, the corneal opacity is called *nebula* (Fig. 138), when faint and cloud-like, often overlooked until examined by oblique illumination; *macula* (Fig. 139), when more pro-

nounced and appreciable as a gray spot in daylight; *leucoma* (Fig. 140), when dense and white. When the iris is attached to the scar tissue, the condition is spoken of as *adherent leucoma* (Fig. 128, Plate X).

Opacities of the cornea interfere with perfect vision when they involve or encroach upon the pupillary area, the degree

FIG. 138. —Corneal Nebula. FIG. 139.—Corneal Macula. FIG. 140.—Corneal Leucoma.

depending upon their density. Even slight opacities cause considerable *visual disturbance* on account of the resulting diffusion of light. Denser opacities cause *disfigurement*.

Treatment.—Various measures are used to reduce the density of corneal opacities, or, if faint, to cause their disappearance. Such remedies are of value only when the opacity is *recent* (less than one year); they act most successfully in children and when the change is superficial. Most commonly the *ointment of the yellow oxide of mercury* is placed in the conjunctival sac, after which the cornea is *massaged* for a few minutes, and then *hot compresses* are applied. Diluted tincture of opium, turpentine, and other *irritants* are used for this purpose. Electricity has been recommended.

When such measures are unsuccessful, and the leucoma entirely occludes the pupillary area, iridectomy for *artificial pupil* may be performed, the coloboma being made opposite a clear part of the cornea.

To remove the disfigurement in cases of leucoma, *tattooing* is often resorted to. The eye is anæsthetized, and the leucoma covered with a thick paste of India ink; the pigment is

FIG. 141. —Tyson Tattooing-Needles.

FIG. 142.—Grooved Tattooing-Needle.

then introduced obliquely into the corneal substance, either by means of an instrument consisting of a row or bundle of round needles (Fig. 141) or with a grooved needle (Fig. 142). The color fades in the course of a few years and then the operation may be repeated. When the opacity covers only a part of the pupillary area, tattooing is useful in preventing the diffusion of light which is so annoying to the patient. The operation is contraindicated when the cornea is very thin or when likely to increase intraocular disease by irritation.

INJURIES OF THE CORNEA.

These comprise foreign bodies, burns, and wounds.

Foreign Bodies, consisting of iron, coal, ashes, dust, etc., frequently adhere or become embedded in the cornea, causing much pain, lachrymation, and photophobia. When the foreign

body is small, it may be difficult to detect, unless we make use of *oblique illumination*. The mischief which a foreign body provokes depends upon the *depth* to which it penetrates and whether or not it is *infected*. If present for a number of days, a surrounding area of *infiltration* appears, resulting in a small ulcer, and in this manner the foreign body may become dislodged; if it consists of iron or steel, this ring

FIG. 143.—Method of Removing a Foreign Body from the Cornea (Surgeon Standing Behind the Patient).

will become stained by rust. Foreign bodies are sometimes the cause of ulcers of the cornea.

To Remove a Foreign Body.—The eye is cocainized; the patient is seated facing a good light with the surgeon standing *behind* and supporting the head; the lids are separated and

the eyeball is steadied by the fingers of the left hand; the index finger is applied to the margin of the upper lid and the middle finger to the lower lid, and the two fingers are separated, at the same time gently pressing backward (Fig. 143). If the patient is seated in a chair provided with a suitable head-rest, the surgeon may stand *in front* and to the left; under such circumstances, the index finger is applied to the lower lid and the middle finger to the upper (Fig. 144).

The *instruments* used are either the blunt spud, the gouge, or the foreign-body needle (Figs. 145-147); these should be *sterilized* before use.

When the foreign body is superficial, the *blunt spud* will answer; very often the particle can be removed with a little *absorbent cotton* wound around the end of the spud. When it has penetrated into the corneal substance, it must be

FIG. 144.—Method of Removing a Foreign Body from the Cornea (Surgeon Standing in Front and to the Left of the Patient).

FIG. 145.—Foreign-Body Spud.

FIG. 146.—Foreign-Body Gouge.

FIG. 147.—Foreign-Body Needle.

picked or dug out with the *gouge*, or the *needle*; in such cases, the instrument is passed *behind* the foreign body. The wound which results must be kept *clean* by frequent irrigation with solution of boric acid; frequently a protective bandage is indicated. If a ring of *rust* is present, this also should be removed. Care must be taken to inflict as

little injury as possible, and when the foreign body is deep, *not to perforate the cornea*. If it penetrates into the anterior chamber, a keratome (Fig. 183) should first be passed through the cornea and behind the foreign body, so that the latter will not be pushed into this space during efforts at removal.

Burns of the cornea are treated like similar conditions of the conjunctiva (p. 110).

Wounds may be non-penetrating or penetrating. *Non-penetrating* wounds are most commonly abrasions due to scratches with the finger nail, twig of a tree, or the like. Such injuries, though very *painful*, heal readily unless infected; they should be kept clean by frequent *irrigation* with solution of boric acid; a *bandage* may be indicated, and sometimes *atropine*.

Perforating Wounds are more *serious* owing to the danger of prolapse of the iris and injury to the deeper parts. They should be treated by thorough *cleansing*, *atropine* or *eserine* according as they are central or peripheral, and a *pressure bandage*. If extensive, the edges may be stitched together.

CHAPTER IX.

DISEASES OF THE SCLERA.

Anatomy.—The *sclerotic* coat (sclera) is the tunic which with the cornea forms the external fibrous layer of the eyeball; it is strong, opaque, and inelastic, and serves to maintain the form of the globe. Its *thickness* is about 1 mm., but varies at different points. Its *structure* resembles that of the cornea, being composed of bundles of *connective tissue* with some elastic fibres, disposed in both longitudinal and transverse layers; these are connected by cement substance containing cell spaces in which are lodged connective-tissue corpuscles; these parts are, however, much less regularly arranged than in the cornea. In the child, the sclera often has a bluish-white color, owing to its being thinner and allowing the dark pigment of the choroid to show through. The sclera is pierced about 2.5 mm. internal to the posterior pole of the eye by the optic nerve; here it has blended with it the external fibrous sheath of the nerve. The part through which the nerve passes is known as the *lamina cribrosa*.

The outer surface of the sclera is white and smooth, covered by *Tenon's capsule* and the conjunctiva, to which it is joined by *loose connective tissue (episcleral)*; in front, it presents the insertions of the extrinsic muscles of the eyeball. Its inner surface is brown and rough, being covered by delicate, pigmented connective tissue, which is united to the choroid by filaments traversing the lymph space existing between the sclera and choroid; where it is pierced by vessels and nerves, a communication between the capsule of Tenon and the suprachoroidea is established. Though traversed by many blood-vessels, the sclera itself has a very scant vascular supply; but the episcleral tissue contains numerous vessels.

Affections of the Sclera include superficial inflammation (episcleritis), deep inflammation (scleritis), staphyloma, and injuries.

Inflammation of the Sclera (Scleritis) may be either superficial or deep. The *superficial* form, called *episcleritis*, is limited to the tissues superficial to the sclera and is relatively harmless. The *deep* form, known as *scleritis*, involves the

sclera itself and extends to subjacent and contiguous parts, causing serious consequences. There is often an absence of a very sharp line of division between the two forms.

EPISCLERITIS.

An inflammation of the *subconjunctival connective tissue*.

Symptoms.—There are *discomfort, lacrymation*, slight pain, and photophobia. A flat or somewhat raised inflammatory *patch of a purple color* is seen, usually on the temporal side, adjacent to the cornea or a short distance from the limbus (Fig. 117, Plate IX). There is no tendency to suppuration or ulceration. After a few weeks, the purple spot will disappear; but others are apt to take its place; in this way the process may encircle the cornea. Owing to this tendency to *relapses*, the disease often lasts *many months*. Sometimes some discoloration of the sclera remains, but there is no interference with vision. Occasionally the adjacent portion of the cornea is implicated. The disease may resemble a marked case of *phlyctenular conjunctivitis*; it may merge gradually into *scleritis*.

Etiology.—It is usually observed in *adults*, especially in women. It is often found in *rheumatic* and *gouty* individuals. Syphilis, tuberculosis, and menstrual disorders are predisposing factors.

Treatment should be of a *sedative* nature: *Warm compresses*; if photophobia be pronounced, smoked coquilles; if the cornea be implicated, atropine. The occasional instillation of one-per-cent. solution of *holocain* in 10,000 *adrenalin* will relieve the discomfort. The ointment of the *yellow oxide of mercury* (one per cent.) applied with gentle massage, and the *subconjunctival injection* of physiological salt solution are sometimes of value, especially when the disease shows a tendency to become obstinate. When there is a rheumatic history, *sodium salicylate* or *aspirin* (gr. x. every two or three hours), should be given; even when this diathesis is absent, these remedies may be useful. Other constitutional disorders should be prescribed for. *Iodide of potassium* may be ordered, also hypodermic injections of *pilocarpine*.

Transient Periodic Episcleritis is a variety of episcleritis which appears in sudden attacks lasting several days, reappears at intervals of several weeks or months, and may recur for years. It is seen in gouty and rheumatic adults. The treatment is that recommended for episcleritis.

SCLERITIS.

An inflammation of the sclera, in which the symptoms are *acute*, the course is *prolonged*, and the consequences are *serious*. In this disease the sclera itself is involved in the inflammatory process; it becomes *softened*, thinned, and bulging, and *staphyloma* results. Both eyes are frequently involved. *Relapses* are very common.

Symptoms.—*Pain*, usually severe, and frequently radiating to neighboring regions, *tenderness* over ciliary region, *lacrymation*, and *photophobia*. The *tension* of the eyeball is frequently increased; secondary glaucoma often ensues.

There are well-marked dusky or *violet patches* adjacent to the cornea, often extending to the equator, and frequently surrounding the limbus.

Complications.—The *cornea* is frequently implicated and ulceration and opacity follow. Not uncommonly there are *iritis*, *cyclitis*, *choroiditis*, opacities of the vitreous, and secondary glaucoma; the combination of such complications is known as *anterior uveitis*. As a result of these changes, *vision* is often *seriously interfered with* and sometimes lost. The thinning of the sclera results in *staphyloma* of the anterior portion of the globe, which presents a bluish appearance, and causes myopia.

Etiology.—The disease is most common in *adults*, and especially in women. *Rheumatism* and gout, syphilis, tuberculosis, and disorders of menstruation are predisposing factors. Exposure to cold is sometimes the exciting cause.

Treatment comprises the measures advocated in episcleritis, energetically applied. The eyes must obtain complete *rest*. *Atropine* is often indicated for the complications. After the

acute symptoms have subsided, an *iridectomy* is sometimes advisable for diminishing glaucomatous tension or reducing the staphyloma.

STAPHYLOMA OF THE SCLERA.

A *thinning and bulging* of the sclerotic occurring either at the anterior portion, the equator, or the posterior portion of the eyeball.

Anterior and Equatorial Staphylomata are usually secondary to inflammations of the uveal tract and sclera which have caused softening of the sclera with or without increased tension. They present a *bluish-gray* bulging which may be limited or may extend all around the cornea (Fig. 148). This bulging shows a tendency to increase; occasionally it bursts. *Iridectomy*, if feasible, is the only treatment, and is done for the purpose of arresting the process. In some cases, when the enlarged eyeball causes much

FIG. 148.—Anterior Staphylomata of the Sclera.

discomfort and is sightless, *enucleation* or *evisceration* is advisable.

Posterior Staphyloma is of common occurrence and is generally associated with myopia and choroiditis (p. 156). It is seen with the ophthalmoscope, presenting a white crescentic or irregular patch which embraces the temporal side of the optic disc (Fig. 165, Plate XIII, and Fig. 168, Plate XIV).

INJURIES OF THE SCLERA.

The important injuries include *rupture* and *perforating wounds*; these are *serious* on account of the danger of escape of the contents of the eyeball and infection of the interior.

Small, clean, perforating wounds often heal without reaction, and require no other treatment than *cleansing* and the application of a *bandage*.

Large, gaping wounds and ruptures frequently allow escape

of the vitreous. There will be blood in the vitreous, diminished tension, and some of the underlying tissues (choroid, ciliary body, or iris) varying with the position, will be found in the wound. Such wounds should be *cleansed*, the *prolapsed parts returned* when not too seriously injured, and the opening *closed* by sutures in the sclera or preferably through the conjunctiva; the patient must remain absolutely *quiet* and the eye should be *bandaged*.

Sometimes such wounds fail to excite much inflammatory reaction; then they heal quite readily, often with incarceration of the prolapsed parts in the scar. But frequently they give rise to *panophthalmitis* with ultimate phthisis bulbi, or to plastic *iridocyclitis* with loss of sight. When the wound involves the ciliary body, iridocyclitis is apt to be set up, and the injury becomes more dangerous on account of the liability of such wounds to excite sympathetic ophthalmitis.

Ruptures of the sclera are produced by blows and blunt instruments; they usually occur near the corneal margin, generally above. The conjunctiva may not be broken.

When injuries of the sclerotic are *very extensive* and cause considerable loss of contents of the eyeball, and when we believe that useful sight cannot be hoped for, the *eyeball* should be *removed* at once. This becomes still more urgent when the wound involves the dangerous zone, the ciliary region.

The presence of a *foreign body* in the eye is a serious complication. The attempt should be made to extract the particle, as described on p. 189.

CHAPTER X.

DISEASES OF THE IRIS.

Anatomy and Physiology.—The second or vascular coat of the eye (*uvea or uveal tract*) lies immediately beneath the sclera; it provides for the nourishment of the eyeball, and it is formed of three parts, which from before backward are known as the *iris*, the *ciliary body*, and the *choroid*. These three portions are so *intimately associated* that when one part becomes diseased, the others frequently participate.

The Iris is a colored membrane, circular in form, hanging behind the cornea immediately in front of the lens, and perforated in its centre by an aperture of variable size, the *pupil*; it serves to regulate the amount of light admitted to the interior of the eye, and cuts off the marginal rays which would interfere with the sharpness of the retinal image. Its peripheral border springs from the head of the ciliary body and the ligamentum pectinatum. Its free inner edge, the boundary of the pupil, lies upon the anterior capsule of the lens when the pupil is contracted or moderately dilated; with maximum dilatation of the pupil it hangs free in the anterior chamber. The iris separates the *anterior* from the *posterior chamber* of the eyeball. Its anterior surface presents great variation in *color* in different eyes, and is marked by radially directed, wavy lines, converging toward the circle of irregular elevations and small depressions (crypts) situated near the pupil; other finer lines are seen extending from this ring to the pupil. This appearance is produced by the subjacent blood-vessels.

In *structure*, the iris consists of a delicate, spongy connective-tissue stroma, containing branched pigmented cells, muscular fibres, and an abundance of vessels and nerves; it is covered anteriorly by endothelium, and posteriorly by the posterior limiting membrane and the retinal pigment layers.

The *color* of the iris depends partly upon the pigment in the stroma cells, which is variable, and partly on that in the cells of the retinal layers, which is constant.

The muscular tissue, the *sphincter pupillæ*, is a narrow band, about one millimetre wide, situated close to and encircling the pupil posteriorly, and supplied by the *third nerve*. The *posterior limiting membrane* consists of fibres which extend from the ciliary to the pupillary margin, which are regarded by some authorities as consisting of unstripped muscle fibres and as contributing to the active dilatation of the pupil. The chief factor in active *dilatation of the pupil* is, however,

the contraction of the thick *muscular coats of the arteries*, under the control of the *sympathetic*.

The *posterior surface* of the iris is covered by two strata of pigmented cells, the uveal layer, which extends to the free border around which it turns a little, forming the black fringe of the pupillary margin.

The *vessels* of the iris come from the two branches of the ophthalmic known as the long posterior ciliary arteries; each artery divides into an upper and a lower branch; these anastomose with the corresponding vessels of the opposite side and with the anterior ciliary, and form a vascular ring just behind the attached margin of the iris, the greater vascular circle of the iris. This gives off branches to the ciliary body and iris; the iris branches converge toward the pupil and here form by anastomosis a smaller vascular circle, the lesser vascular circle of the iris. The veins of the iris follow the arrangement of arteries just described; in addition they communicate with the canal of Schlemm; they chiefly pass backward to the *venæ vorticosæ*.

The *nerves* are given off from the plexus in the ciliary body, and are derived from the third, the nasal branch of the ophthalmic, and the sympathetic.

Pupillary Membrane.—In the fœtus the pupil is closed by a thin, transparent, delicate membrane—the pupillary membrane. The membrane and its vessels are gradually absorbed in the seventh or eighth month of fœtal life. A few shreds may remain at birth; occasionally part or all of the membrane persists (persistent pupillary membrane).

IRITIS.

An *inflammation of the iris* which may be divided into the following

Varieties: (a) According to its *course*, into (1) Acute, (2) Subacute, and (3) Chronic.

(b) According to the *pathological products*, into (1) Plastic, (2) Serous, (3) Purulent, and (4) Tuberculous.

(c) According to its *etiology*, into (1) Syphilitic, (2) Rheumatic, (3) Gouty, (4) Diabetic, (5) Gonorrhœal, (6) Tuberculous, (7) Traumatic, (8) Sympathetic, (9) Secondary, and (10) Idiopathic.

The classification according to the nature of the pathological products is unsatisfactory because one type merges into the other. It is better, therefore, to consider *Iritis In General*, and then to mention the peculiarities of the different forms which have been named according to their etiology.

Objective Symptoms (Figs. 150, 151, 152, Plate XI).-- The iris looks *altered*. It appears *swollen, dull*, loses its lustre, its markings become *indistinct*, its *color changes* and becomes greenish in blue or gray irides, and muddy in darker varieties.

FIG. 155.—Posterior Synechiæ Causing Irregular Pupil in Iritis.

These changes are due to *congestion* of the iris and *exudation* of cells and fibrin into its substance; also to exudation into the anterior chamber.

The *pupil* is *contracted, grayish, sluggish* in action, and *irregular* (Fig. 155); the last peculiarity is due to *adhesions* between the

posterior surface of the iris and the anterior capsule of the lens (*posterior synechiæ*), best seen after the instillation of atropine.

The contents of the *aqueous chamber* show changes; there is frequently *turbidity*; there may be more or less dust-like *deposit* on Descemet's membrane (so-called *keratitis punctata*), which often involves the lower part (Fig. 152, Plate XI) or may give a cloudy appearance to the entire cornea. In this exudation there may be *pus* which then gravitates to the bottom (*hypopyon*) or *fibrin*, which coagulates into a grayish mass (*spongy iritis*), or there may be *blood* (*hyphæma*). The *anterior chamber* may be *deeper* than normal. The *tension* of the eyeball, though usually normal, may be increased.

The anterior capsule of the *lens* may present evidences of exudation, and also small *spots of uveal pigment* where posterior synechiæ have been torn away.

There is always marked *circumcorneal injection*, and with this pink zone there is more or less conjunctival congestion.

Subjective Symptoms consist of *pain, photophobia, lachrymation, interference with vision*, and sometimes general malaise.

The *pain* is often severe, neuralgic in character, radiating to the forehead and temple, and worse at night. It is some-

Figs. 149-154.—Iritis. Panophthalmitis.

times accompanied by *tenderness* of the eyeball, a symptom pointing to involvement of the ciliary body.

The diminution in the acuteness of vision depends upon the cloudiness of the anterior chamber and the deposits in the pupil and upon Descemet's membrane. When very marked, it indicates extension of the inflammation to the *deeper parts*.

Differential Diagnosis.—Iritis is most frequently mistaken for *acute catarrhal conjunctivitis*. Sometimes *acute glaucoma* is mistaken for iritis. The differential points are given in the following tables:

<i>Acute Iritis.</i>	<i>Acute Conjunctivitis.</i>	<i>Acute Glaucoma,</i>
1. Iris swollen, dull, and discolored.	1. No change in iris.	1. Iris congested, discolored, dull, periphery pushed forward.
2. Pupil small, gray, sluggish, irregular after use of atropine.	2. Pupil normal.	2. Pupil dilated, oval, immobile.
3. Anterior chamber of normal depth (deeper in serous form) and presents exudation.	3. Anterior chamber normal.	3. Anterior chamber shallow and aqueous sometimes turbid.
4. Cornea transparent (may present deposits on posterior surface) and sensitive.	4. Cornea transparent.	4. Cornea steamy and insensitive.
5. Ciliary (circumcorneal) injection; pink zone of fine vessels surrounding cornea and fading toward fornix.	5. Conjunctival injection, coarse meshes, most pronounced in fornix and fading toward the cornea.	5. Ciliary and episcleral injection (also conjunctival congestion).
6. Conjunctiva usually transparent.	6. Conjunctiva reddened and opaque.	6. Conjunctiva congested and chemotic.
7. Lacrymation but no discharge.	7. Mucous or muco-purulent discharge.	7. Lacrymation but no discharge.
8. Tension usually normal (occasionally increased).	8. Tension normal.	8. Tension increased.
9. Some ciliary tenderness.	9. No ciliary tenderness.	9. Ciliary tenderness.
10. Pain radiating to forehead and temple, worse at night.	10. Discomfort, hot gritty feeling, but no real pain.	10. Severe pain in and about eye, with headache.
11. Dimness of vision.	11. No interference with vision, except blurring caused by the discharge smeared over the surface of the cornea.	11. Marked dimness of vision.

Course.—Iritis may be *acute* and run its course in several weeks; or it may be *chronic* and last a number of months. A great many cases terminate favorably, especially when subjected to proper treatment early; the exudation becomes absorbed, and the iris returns to a normal condition with no evidences or mere traces of former inflammation. Chronic cases present very mild inflammatory symptoms, or the latter may be entirely absent. Certain forms of iritis have a tendency to recur. Iritis may involve *one* or *both eyes*; when both eyes are attacked, the second usually is affected a short time after the first.

Complications.—The *neighboring parts of the eye* are sometimes involved in severe forms of iritis: conjunctiva, cornea,

ciliary body, choroid, vitreous, optic nerve, and retina. The association of inflammation of the ciliary body (*cyclitis*) with iritis (*iridocyclitis*) is so common, that some authors describe the two conditions together and regard pure iritis as rare. The following symptoms, occurring in the course of an iritis, point to the *existence of cyclitis*: Violent inflammatory symptoms, marked diminution in vision, tenderness in the ciliary region, deposits upon the posterior surface of the cornea, and increase or decrease of normal tension.

Sequelæ.—These are often *posterior synechiæ* and *deposits* upon the anterior lens capsule; less frequently there are *exclusion of the pupil*, *occlusion of the pupil*, *atrophy of the iris*, *opacities of the vitreous*, *deposits upon the posterior capsule of the lens*, and *cataract*. In *exclusion of the pupil* (an-

FIG. 156.—Section of the Anterior Portion of the Eyeball showing the Iris in its Normal Relations.

FIG. 157.—Section showing Annular Posterior Synechia (Exclusion of the Pupil.)

FIG. 158.—Section showing Total Posterior Synechia and Occlusion of the Pupil.

nular posterior synechia), the iris is bound down throughout its entire pupillary margin, the pupil remaining clear (Fig. 157); this causes a loss of communication between the anterior and the posterior chamber; the aqueous secreted by the ciliary processes is hemmed in, the iris stretched (*iris bombé*) and

atrophied, *glaucoma* results, and if unrelieved, blindness follows. *Occlusion of the pupil* is a filling in with opaque exudate (Fig. 158).

Etiology.—Iritis may be *primary*, or may be *secondary* to affections of neighboring structures. Primary iritis is frequently dependent upon some *constitutional disease*: very often *syphilis* and *rheumatism*; much less frequently, gout, tuberculosis, gonorrhœa, acute infectious diseases, and diabetes. It may also be traumatic, sympathetic, and often is *idiopathic*.

Treatment.—(1) Atropine, (2) leeches, (3) hot fomentations, (4) rest, (5) protection from light, (6) treatment of etiological factor.

Atropine diminishes the congestion of the iris, puts this part at rest, causes mydriasis, and thus prevents adhesions and tends to break up those which have already formed. It should be instilled every two hours at first, and after the pupil is dilated, three or four times a day. When the inflammation is pronounced, the pupil will not dilate rapidly. The action of atropine is often increased by the addition of cocaine. In certain cases, symptoms of *atropine poisoning* (p. 366) occur, either local or constitutional, necessitating the substitution of some other mydriatic (duboisine, hyoscyamine, scopolamine); a solution of the aqueous extract of belladonna (1:8) often acts well in such cases. Exceptionally atropine causes an increase in inflammatory symptoms and must be stopped; then

FIG. 159.—Artificial Leech.

a *miotic* may be of service; this action is apt to occur when there is increased tension, and sometimes when there is a complicating cyclitis.

Two or three *leeches* applied to the temple, or the abstrac-

tion of an ounce of blood from this region by means of the *artificial leech* (Fig. 159), usually have a favorable effect.

Moist, hot compresses for several hours each day diminish the pain and the inflammation. In traumatic iritis, iced compresses may be used.

Absolute rest in bed is indicated in the early stage of acute iritis and is an important aid in treatment.

Protection from light, by means of smoked coquilles or a shaded room, is essential.

Other important indications are light *diet*, abstinence from alcoholics, a brisk *purge*, and avoidance of all use of the eyes for near work.

Constitutional Treatment must meet the indications in the different forms. In *syphilitic* iritis *mercury* is given, usually by inunction, up to the point of salivation; after the acute symptoms have subsided, *mixed treatment* (mercury and iodide of potassium) is substituted. In certain apparently idiopathic forms, small doses of mercury have a favorable effect. In rheumatic cases we prescribe large doses of *salicylate of sodium*; this remedy also has a quieting effect upon the pain in other forms.

Paracentesis is occasionally resorted to for the purpose of relieving tension, and also in obstinate cases to produce a favorable effect upon the progress of the disease. *Iridectomy* is sometimes performed for the same reasons. As a rule, however, operative procedures are useful only after the inflammatory symptoms have subsided, for the purpose of remedying sequelæ.

It remains to consider briefly the distinctive features of certain varieties of iritis.

Clinical Varieties.—*Syphilitic Iritis* is the most common form. It occurs in the *secondary* stage of acquired syphilis; it is usually *acute*; the second eye is apt to become involved at a varying interval after the first one has become affected; there is more or less *plastic* exudation; in some cases there are yellowish, vascular *nodules* usually situated at the pupillary border of the iris (Fig. 151, Plate XI); *pain is not pronounced*; if properly treated, relapses are not common.

Rheumatic Iritis is usually *acute*; it frequently attacks only *one eye*; it occurs especially in adults; the effusion is *serous* with a few cells; *pain is pronounced*; *relapses* are common.

Gonorrhœal Iritis is occasionally seen in persons suffering from gonorrhœa or gleet; it resembles rheumatic iritis.

Idiopathic Iritis is the name given to a great number of cases in which we can find no cause; it occurs usually in adults, and generally attacks one eye. Many of these cases derive great benefit from anti-syphilitic treatment.

Suppurative Iritis presents *hypopyon*; it is often *traumatic*; if *infected*, the process is merely part of a *panophthalmitis*.

Tuberculous Iritis is rather rare. It occurs in *young persons*, is apt to be *subacute* in course, *obstinate*, and presents *tuberculous nodules*, which are, as a rule, near the attached border of the iris. There are often constitutional manifestations of *tuberculosis*, though sometimes there are no demonstrable signs of implication of other parts of the body.

Tumors of the Iris may be (1) *inflammatory*: *a*, syphilitic, *b*, tuberculous, both of which have just been described; and (2) *new growths*: cysts, melanoma, and sarcoma, all of which are rare.

Injuries of the Iris may be (1) non-perforating and (2) perforating.

(1) *Non-perforating injuries* (concussion, blows upon the eyeball) may cause (a) *mydriasis* (as a result of paralysis of the sphincter of the iris, iridoplegia), (b) a *tear* in the pupillary margin, in both of these cases eserine being indicated; (c) *iridodialysis*, a separation of the ciliary border of the iris (Fig. 160), for which atropine is required.

FIG. 160.—Iridodialysis.

(2) *Perforating injuries* are usually complicated by wounds of the lens and other parts of the eye. A perforating wound of the eyeball may lacerate the iris or merely allow the latter to project through a wound of the cornea or of the ciliary region (*prolapse*). In cases of prolapse, the wound must be irrigated with a mild cleansing lotion, such as boric acid or weak bichloride; if seen early, within a few hours, and there is no injury to iris and lens, the iris may be returned into the anterior chamber, atropine or eserine used according to the seat of the perforation, and a bandage applied. If there is little hope of saving the prolapsed portion of the iris, it should be excised, the cut edges carefully separated from the wound by a spatula, atropine or eserine used according to the seat of the injury, and the eye bandaged.

Operations upon the Iris.—*Iridectomy* is the only important operation upon the iris. It is described with glaucoma (p. 177), which forms its most frequent indication.

Iridotomy and *Iridocystectomy* are operations the indications for which occur very infrequently, when, after loss of the lens following injury or cataract operation, the pupil has been closed by inflammation or been drawn toward the cicatrix. In *iridotomy*, the iris fibres are cut transversely with a Graefe knife or with special forceps-scissors introduced through a small corneal incision. In *iridocystectomy*, an incision is made through the cornea, and the capsule and the edge of the iris are drawn out by means of a blunt hook or forceps, and cut off. The object of both operations is the formation of an *artificial pupil*. However perfect the operative effect may be, the visual result is often marred by deeper changes caused by the previous inflammation.

THE PUPIL.

The normal pupil is circular and regular in outline. It is larger in the young than in advanced life. Its size should equal that of its fellow; both should respond alike when one is subjected to a change in intensity of illumination. The movements of the pupil are contraction and dilatation.

The *contracting fibres* of the iris, the *sphincter pupillæ*

(muscle), are supplied by the *third nerve*. The *dilating* fibres in the posterior limiting membrane are supposed to be supplied by the *sympathetic*. The *blood-vessels* of the iris, also supplied by the sympathetic, constitute the principal agents in active *dilatation* of the pupil; contraction of these vessels causes narrowing of the iris with dilatation of the pupil.

Contraction of the pupil is effected by stimulation of the oculomotor nerve and by paralysis of the sympathetic. *Dilatation* follows paralysis of the third nerve or stimulation of the sympathetic.

The *oculomotor-nerve fibres* are conveyed through the ciliary ganglion and short ciliary nerves. The nucleus of origin of the third nerve concerned in the movements of the iris is in the floor of the aqueduct of Sylvius, and can be divided into three portions: (1) that giving rise to the sphincter fibres of the *iris*, (2) *accommodation* (ciliary muscle), and (3) *convergence* (internal rectus). The *sympathetic or dilating fibres* are given off from the cilio-spinal centre of the lower cervical spinal cord.

The *pupil contracts* upon exposure to light, with accommodation, and with convergence. The light contraction may be *direct* or *consensual*. The *direct light reflex* is obtained by exposing one eye to increased illumination and observing the contraction of the pupil of this eye. The *consensual or indirect light reflex* is obtained by throwing light into one eye and observing the contraction of the pupil of the other eye. The *accommodation and convergence reflex* is obtained by directing the patient to look at an object held several inches in front of the face in the middle line; the pupils will be seen to contract. These three actions are *associated*.

The *dilatation reflexes* of the pupil are seen upon shading the eye (both direct and consensual), and upon looking at a distant object. In addition there is a *sensory reflex*: when sensory nerves are stimulated, as by scratching or tickling the skin, both pupils dilate.

The *consensual contraction* is explained by the fact that the light stimulus in one eye is carried by the optic nerve and passes to *both* optic tracts, and in this way to the nucleus of

the third nerve of each side (Fig. 161). Blindness in one eye abolishes the direct reflex in this eye, but its consensual reflex is preserved.

In certain pathological conditions, there may be loss of light reflex, without interference with sight. The *Argyll-Robertson pupil* (reflex iridoplegia), so frequently a symptom of locomotor ataxia, contracts with accommodation and convergence, but does not respond to light; it is usually accompanied by miosis.

The characteristics of the pupils—size, equality, and reflexes, are of great value in the diagnosis of various affections of the nervous system and in the localization of cerebral lesions. Hence it is important to be familiar with the afferent and efferent routes which control the movements of the pupil (Fig. 161, and Plate XXI).

FIG. 161. — Visual and Pupillary Reflex Paths. L, Left eye; R, right eye; ON, optic nerve; LT, left optic tract; RT, right optic tract; POG, primary optic ganglia; OMN, oculomotor nuclei; OR, optic radiations; OL, occipital lobe; CIL, ciliary ganglion. Division of the fibres at 1 abolishes the reaction of the pupil to light upon illuminating the left half of either retina. At 2, the same result with right homonymous hemiopia. At 3 right homonymous hemiopia with preservation of the reaction of the pupil to light.

The course of the *afferent impulse* is retina, optic nerve, both optic tracts, corpora quadrigemina, nuclei of origin of the third nerve in the floor of aqueduct of Sylvius (there being a communication between the two sides).

The *efferent impulse* travels on either side from these nuclei to the third nerve, the ciliary ganglion, short ciliary nerves, to the iris.

Mydriatics and Miotics are described in the chapter on Ocular Therapeutics, and on p. 310. The *hemiopic pupillary reflex* is explained on p. 251.

CHAPTER XI.

DISEASES OF THE CILIARY BODY.

Anatomy.—The ciliary body is that part of the tunica vasculosa which extends backward from the base of the iris to the anterior part of the choroid; it consists of the *ciliary processes* and of the *ciliary muscle*. A longitudinal section is of triangular shape, with a narrow base directed forward giving origin to the iris. The outer side of the triangle is formed by the ciliary muscle; the inner side can be divided into two parts: an anterior, which bears the ciliary processes, and a posterior portion, which is smooth.

The *ciliary muscle* (the muscle of *accommodation*) consists of non-striated muscular fibres arranged in bundles, anastomosing with one another frequently so as to form a sort of plexus, and running in three different directions—meridional, radiating, and annular. The proportion between circular and longitudinal fibres varies according to the refractive condition of the eye; the circular set is well developed in hyperopia (Fig. 287), but atrophied in myopia (Fig. 288). When the ciliary muscle contracts, it draws the ciliary processes and choroid forward and inward, thus relaxing the suspensory ligament and allowing the lens to become more convex.

The *ciliary processes* consist of about seventy folds or thickenings, arranged meridionally, so as to form a circle. They have the same structure as the rest of the choroid, but are even more vascular. They serve to *secrete the nutrient fluids* in the interior of the eye which nourish neighboring parts, especially the cornea, lens, and part of the vitreous. The inner surface of the ciliary body is covered by three layers: externally, a homogeneous membrane continuous with the posterior limiting membrane of the iris; next, pigment epithelium; internally, next to the vitreous, a layer of cylindrical non-pigmented cells.

The ciliary body is supplied by branches from the greater circle of the iris and by the anterior ciliary *arteries*. The *veins*, constituting the greater part of the ciliary processes, pass backward to the *venæ vorticosæ* of the choroid. A part of the veins from the ciliary muscle pass backward, pierce the sclera, and run beneath the conjunctiva with the anterior ciliary *arteries*. These constitute the violet subconjunctival vessels seen running backward in ciliary injection and in deeper congestion (glaucoma). They anastomose with the conjunctival veins, and communicate with Schlemm's canal.

CYCLITIS.

As already pointed out, iritis is frequently associated with cyclitis (*iridocyclitis*). While *unmixed cases of cyclitis* occur, they are *uncommon*; usually when the ciliary body is inflamed, the adjacent portions of the uveal tract (iris and choroid) participate, and the disease is, from the start or soon afterward, an *inflammation of iris, ciliary body, and choroid*.

Practically, the term *iridocyclitis* is reserved for those cases in which there are pronounced symptoms of *iritis*, and in addition the following evidences of *participation of the ciliary body*: Tenderness in the ciliary region, swelling of the upper lid, deposits upon Descemet's membrane, abnormal tension, and a greater interference with vision than can be explained by changes in the anterior chamber (due to opacities of the vitreous).

Symptoms.—The symptoms of cyclitis are those of iritis, plus the additional ones just mentioned. Cyclitis or iridocyclitis is always a *serious* affection; the inflammation is pronounced, and the changes in the eye may be *disastrous*; it often causes *destruction* of the eyeball.

Varieties.—Cyclitis may be divided into (1) simple, (2) plastic, and (3) purulent.

Simple Cyclitis is often known as *Serous Cyclitis*, *Serous Iritis*, *Keratitis Punctata*, and *Descemetitis*; all these synonyms are objectionable. This form occurs in *young adults*, is *chronic* in its course, and is likely to *relapse*; it is apt to involve the *second eye* at a variable period after its occurrence in the first.

Symptoms vary a great deal in intensity. They include those of iritis with the special signs mentioned above. The *exudation* consists of serum and of small cells; the latter are apt to adhere to the posterior surface of the cornea (Fig. 152, Plate XI); hence the name *keratitis punctata*. The *anterior chamber* is *deep*, the *aqueous* often *turbid*; there may also be increased *tension* or alternations of increase and diminution of tension; there is often *dilatation* of the pupil; minute *opacities* form in the vitreous and thus *vision* is markedly *diminished*; pain is not apt to be severe.

Complications.—Iritis, choroiditis, scleritis, and glaucoma.

Etiology.—Rheumatism and gout, general debility, anæmia, and tuberculosis.

Prognosis is generally *good*; but there is always danger of glaucoma supervening.

Treatment is that of *iritis*. In some cases, however, *atropine* is not well borne and increases the pain. Under such circumstances there may be increased tension, and then *eserine* or *pilocarpine* can often be substituted with advantage.

Plastic Cyclitis.—This form is accompanied by very *pronounced symptoms of iridocyclitis*; it may be acute or subacute. The *pain* is severe; there is great ciliary *tenderness*; the circumcorneal *congestion* is marked, the color being often purplish as in episcleritis; the *anterior chamber* is *deep*; the *pupil* is often *dilated* owing to the retraction of the periphery of the iris by the plastic exudation; *tension* is reduced, or there may be alternations of + and — tension.

The disease is rarely limited to the ciliary body; it spreads through the entire uveal tract and then constitutes *plastic uveitis*. The *exudation* is formed in the anterior chamber, pupil, behind the iris, and in the vitreous; it contracts subsequently and causes *detachment of the retina* with complete *blindness*.

The degenerated eyeball shrinks, and the condition is then known as atrophy of the eyeball. The affection may now become quiescent; but from time to time there are apt to be *attacks of pain*, and the shrunken eyeball is often a *constant menace to the other eye*. This form of inflammation has a great tendency to cause sympathetic uveitis in the other eye (*sympathetic ophthalmitis*). Though the disease is capable of being cured in the early stages and leaving the eye in a more or less useful condition, the majority of such eyes are *lost*.

The *cause* is usually an *injury in the ciliary region*, either as a result of violence or after operations upon the eyeball, especially cataract extraction. The *treatment* is that recommended for *iritis*.

Purulent Cyclitis is an inflammation of the ciliary body with the formation of *pus*. Strictly speaking, it is always an iridocyclitis and as such can be divided into two varieties.

In the *non-septic form*, the term "purulent" merely refers to the presence of pus in the anterior chamber; the course of the disease resembles that of acute iritis, and its *prognosis* is equally *favorable*.

In the second class of cases, the one usually meant when purulent iridocyclitis is spoken of, there is a *septic inflammation* of the ciliary body, iris, and usually choroid, with the formation of *pus*. Such an inflammation may be set up by *septic emboli* after pyæmia and puerperal septicæmia, and also occurs after meningitis and cerebro-spinal meningitis in children (*metastatic*). But the usual cause of purulent iridocyclitis is an *injury in the ciliary region*, including operative wounds; also *infected ulcers* of the cornea.

The *symptoms* are always *pronounced*. Besides those present in a severe case of iridocyclitis, there is apt to be marked congestion of the conjunctiva with chemosis, and swelling of the lids. Pus forms in the anterior chamber and in the vitreous; if the usually clouded cornea and aqueous permit, a *yellow reflex* is obtained from the vitreous.

Though the disease may yield to treatment when seen early, the *prognosis* is always *grave*. The cases following pyæmia, septicæmia, and meningitis soon involve the entire uveal tract in the purulent process and terminate in *blindness*, shrinking of the eyeball causing *atrophy* of the globe. In other cases the disease extends to all the structures of the eyeball and terminates in *panophthalmitis* (p. 162). The *treatment* is that of iritis.

Injuries of the Ciliary Body.—The *ciliary region*, represented by a ring about 6 mm. wide around the cornea, is known as the "*dangerous zone*," because penetrating wounds in this situation are apt to set up *plastic cyclitis*, which may be followed by *sympathetic ophthalmitis*. In wounds of this region, if there be no prolapse of the ciliary body and no foreign body in the eye, a *bandage* may be applied after thorough *cleansing*, and a suture used if the wound be large and gaping. Prolapses of the iris and ciliary body are usually abscised. Additional details of treatment are given in the paragraph on Sympathetic Ophthalmitis (p. 159).

CHAPTER XII.

DISEASES OF THE CHOROID.

Anatomy and Physiology.—The choroid is a *dark brown membrane* placed between the sclera and the retina. Anteriorly it is continued into the iris, but before passing into the latter it presents a number of thickenings, the *ciliary processes*, which, with an underlying zone of unstriped muscular tissue, the *ciliary muscle*, constitute the *ciliary body*.

The choroid itself extends from the ora serrata to the aperture for the optic nerve. It consists mainly of *blood-vessels*, united by delicate connective tissue containing numerous *pigmented cells*; these vessels are arranged according to their calibre into three superimposed layers.

This vascular structure is bounded on either side by a non-vascular membrane; accordingly, the choroid can be divided into *five layers*: (1) Externally, the *suprachoroid*, a non-vascular membrane connected with the sclera by loose connective tissue, vessels, and nerves. (2) The layer of *large vessels*; the spaces between these are filled with connective tissue and cells. The arteries are the short ciliary. The veins are arranged in curves (*vasa vorticosa*) converging to four or five principal trunks which pierce the sclera near the equator of the eyeball. (3) The layer of *medium-sized vessels*. (4) The layer of *capillaries* (chorio-capillaris). (5) The *lamina vitrea*, a structureless, transparent membrane which is placed next to the pigmentary layer of the retina.

The *function* of the choroid is chiefly to serve as a *nutrient organ* for the retina, vitreous, and lens. It forms the *dark coating* of the interior of the eyeball.

Inflammations of the Choroid (choroiditis) may be (1) *exudative or non-purulent*, and (2) *purulent*.

EXUDATIVE, NON-PURULENT, OR PLASTIC CHOROIDITIS.

Varieties.—Exudative choroiditis (Plates XII, XIII, XIV) occurs under the following principal forms: (1) *Diffuse*, (2) *Disseminated*, (3) *Central*, including the *myopic* and *senile* varieties, and (4) *Syphilitic*. In many instances, the disease involves the retina as well as the choroid, and is then prop-

erly spoken of as *choroidoretinitis* or *retinochoroiditis*. It will be of advantage to describe *Exudative Choroiditis in General*, before giving the distinctive features of the several varieties.

Subjective Symptoms.—There are *disturbances of vision*, both *diminution* in acuteness, the appearance of spots, and *distortion* of objects (*metamorphopsia*); the latter symptom may

FIG. 162.—Peripheral Scotomata in Exudative Choroiditis.

be divided into *micropsia*, when objects appear too small, and *macropsia*, when they appear too large. There are often *flashes* of light, sparks or bright circles before the eyes. In the later stages there may be *defects in the field* of vision, both *scotomata* (Fig. 162) and *peripheral contraction*. There is no pain.

Objective Symptoms.—There are no external signs, but the *ophthalmoscope* reveals a well-marked picture. There are patches of *exudation* of plastic material, varying in size and position. At first these areas are *yellowish* or yellowish-white in color, with *ill-defined margins*; the retinal blood-vessels are seen to be lifted and to pass over them. Later, after several weeks or months, the exudation becomes absorbed, leaving patches of *choroidal atrophy*. The latter appear as *whitish* areas (the sclera showing through) often marked with distinctly visible choroidal vessels. The atrophic spots are of various shapes and more or less *pigmented*. Not infrequently the *vitreous* is involved, and then there are *opacities* of this medium. Very often the *retina* becomes atrophied opposite the patches just described. The *optic disc* may participate in the changes and present a yellowish-white, dirty color—a condition often spoken of as “*choroidal atrophy*.” The *sclera* may become involved and yield, causing a bulging or *staphyloma*.

Complications.—From this description it will be seen that *neighboring structures* are frequently implicated: Iris, retina, vitreous, and sclera; choroiditis may also cause posterior polar cataract.

PLATE XII.

FIG. 163.—Diffuse Exudative Choroiditis.

FIG. 164.—Disseminated Choroiditis.

PLATE XIII.

FIG. 165.—Choroiditis of Myopia.

FIG. 166.—Central Choroiditis.

Etiology.—Many cases are due to acquired or hereditary *syphilis*. Many examples are found in *myopia*. Some cases are apparently dependent on tuberculosis and anæmia; in others *no cause* can be found.

Prognosis depends upon the *position of the patches* of exudation with subsequent atrophy. A single patch involving the macular region will seriously impair vision. On the other hand, the process may extend over a considerable part of the fundus and yet vision remain good, if the macula escapes.

Treatment.—*Rest of the eyes*; in acute cases, general bodily rest. *Atropine*. Avoidance of bright light and use of *smoked glasses*. *Iodide of potassium* and *mercury* are used, especially in specific cases, but also in others. General tonics. *Diaphoretics*. In recent cases, local blood-letting behind the mastoid process.

Diffuse Choroiditis (Fig. 163, Plate XII).—In this form the patches of exudation are of considerable size; later, the coalescence of the atrophic spots forms a large area of white or yellowish-white color, more or less pigmented, and allowing some choroidal vessels to show.

Disseminated Choroiditis (Fig. 164, Plate XII) presents numerous round or irregular *spots scattered* over the fundus. The entire fundus may be studded, and yet the vision remain good if the macular region escapes. This form of choroiditis runs a very *chronic* course. After existing a long time, atrophy of the retina and optic nerve may be added.

Central Choroiditis (Fig. 166, Plate XIII) is a form in which the changes are *limited to the macula*, and which occurs most frequently in *myopia of high degree*. It results in *serious interference with vision* and causes *central scotoma*. It also occurs as a result of senile changes (*senile central choroiditis*) and in *syphilis*.

Syphilitic Choroidoretinitis (Fig. 167, Plate XIV) is the name given to a *diffuse* inflammation of the choroid, associated with *retinitis* and changes in the *vitreous*, which occurs in the secondary stage of syphilis. At first there are diffuse *cloudiness* of the retina, numerous *exudations* in the choroid, especially in the region of the macula, and fine, *dust-like opacities*

of the vitreous. Later, the cloudiness of the retina is replaced by *atrophy*, there are atrophic patches of the choroid, spots of *pigment*, and *opacities* of the vitreous.

Choroiditis of Myopia ; Posterior Staphyloma, or Sclerochoroiditis Posterior.—The fundus of nearsighted eyes, especially if the myopia be of high degree, very often presents characteristic changes (Fig. 165, Plate XIII, and Fig. 168, Plate XIV). Owing to the elongation of the eyeball, there is a *bulging of the sclerotic* at the posterior pole and *atrophy of the choroid* in this situation. This shows itself in a white crescent (*myopic crescent*) situated usually to the outer side of the disc, varying in size, and sometimes encircling the papilla. It is known as posterior staphyloma or sclerochoroiditis posterior; it is often incorrectly called "*conus*."

When this crescentic or annular patch is separated from healthy choroid by a sharply defined margin, often pigmented, it is a sign that the process has come to a standstill. But when the border is ill-defined, it indicates that the changes are advancing (*progressive myopia*); such knowledge is of great importance in emphasizing the necessity for attention to ocular and general hygiene. The size of the staphyloma is usually, but not always, proportionate to the degree of myopia. More or less *superficial atrophy* of the choroid is often observed in *myopia* of high degree, allowing the larger *choroidal vessels* to become plainly visible. Besides choroiditis in the *macular region*, there may be patches of choroidal atrophy in *other parts* of the fundus; these often coalesce with the posterior staphyloma, so that an extensive white area is seen, spotted or bordered with more or less pigment. The early changes in the macular region may be represented by fine lines or fissures. *Hemorrhages*, especially in the macula region, and *opacities of the vitreous* also occur in myopia of high degree.

The *treatment* consists in *avoidance of near work*, *rest* for the eyes, *smoked glasses*, *outdoor life*, and attention to the *general health*. During the progressive stage, the treatment recommended for choroiditis in general is indicated.

PLATE XIV.

FIG. 167.—Syphilitic Choroidoretinitis.

FIG. 168.—Posterior Staphyloma.

PURULENT CHOROIDITIS.

In this affection, the choroid, ciliary body, and iris are involved in a *purulent inflammation* which leads to the *destruction* of the eyeball. In most cases all the structures of the eyeball are included and *panophthalmitis* results (p. 162).

Symptoms.—Those of *iritis* and *cyclitis* already given, are apt to be *acute* and *severe*. The *pain* may be slight or marked; the *congestion* of the conjunctiva is pronounced, with *chemosis* and *swelling* of the lids. The *cornea* becomes clouded, and *pus* appears in the aqueous and vitreous so that no details of the fundus are visible. *Sight is rapidly lost*.

In those cases in which the process remains limited and panophthalmitis does not result, after the acute symptoms subside, a *sightless, degenerated, and atrophied eyeball* remains. A yellowish or grayish-yellow reflex is then obtained from the interior of the eye, due to the purulent degenerated mass. This is known as *pseudo-glioma* on account of its resemblance in color to glioma of the retina.

Etiology.—It may be due to *metastasis* in pyæmia and puerperal septicæmia; it occurs from *extension* in thrombosis of the orbital veins; it is also found as a complication of *meningitis* and cerebro-spinal meningitis, especially in children. Most cases are due to *infected wounds* of the eyeball from external violence, operations, or after *infective ulcers*.

Treatment resembles the management of iritis. When the disease is the result of an infected wound or ulcer, the electro-cautery may be applied thoroughly and repeatedly; the introduction of small rods of iodoform into the anterior chamber may be of some value. If the process has involved all the ocular structures, the treatment of panophthalmitis is indicated.

Coloboma of the Choroid is a *congenital defect* of the choroid and retina, showing itself in a *large white patch*, representing the exposed sclera; it is usually situated below the disc. The retinal vessels are seen passing across this patch. There is a *scotoma* corresponding to the defect. This condition is often

associated with coloboma (a cleft) in the iris, and a notch at the equator of the lens opposite the coloboma.

Rupture of the Choroid sometimes results from *contusions* of the eyeball. The immediate effect of such an injury is an extravasation of blood into the vitreous. After this is absorbed a long, *yellowish-white streak* with pigmented edges is seen, usually in the neighborhood of the disc and to its outer side.

Tubercles of the Choroid occur in acute miliary tuberculosis and in tuberculous meningitis. They appear as small, yellowish-white spots surrounded by some retinal haze, vary in number, and are found near the disc, in the macular region, or scattered over the fundus. They resemble the spots seen in recent cases of disseminated choroiditis. Tuberculosis occasionally assumes the form of a solitary irregular mass at the macula, which may be mistaken for glioma.

Sarcoma of the Choroid (see Chapter XIV).

CHAPTER XIII.

DISEASES OF THE WHOLE UVEAL TRACT. UVEITIS.

As its name implies, uveitis is an *inflammation of the whole uveal tract*: iris, ciliary body, and choroid. There are two forms: (1) *serous and plastic*, and (2) *purulent*. Both forms have been described in connection with cyclitis, which, as already explained, is generally merely part of a uveitis. There are, however, two special varieties: (1) *Sympathetic Uveitis*, generally known as *Sympathetic Ophthalmitis*, and (2) the form of *Purulent Uveitis* known as *Panophthalmitis*.

SYMPATHETIC OPHTHALMITIS.

Sympathetic Ophthalmitis (sympathetic ophthalmia) is a *serous or plastic inflammation of the uveal tract* in one eye due to the effects of a similar inflammation in the other.

Etiology and Occurrence.—This inflammation is usually due to a *perforation of traumatic, infective origin*, or to *operations* in the *ciliary region*, especially if the iris or ciliary processes be entangled in the wound. *Foreign bodies* in the interior of the eyeball are also apt to excite this disease. Sometimes it results from the iridocyclitis following perforating corneal *ulcers*. Rarely it occurs without any perforating lesion.

It is, fortunately, not of very frequent occurrence, for it is a most *serious* disease, on account of its tendency to cause *blindness*. It occurs most frequently in the young, especially in *children*, but may be met with at any age. It was formerly more common than it is at the present time when asepsis and antisepsis have lessened the danger of its occurrence after operations. It usually begins between *five and eight weeks after the injury* in the exciting eye, rarely before three weeks;

it may, however, occur many months or even years after the injury.

The eye which has been originally affected is known as the *exciting eye*; the one secondarily involved, as the *sympathizing eye*.

Symptoms.—In most cases, but not invariably, the disease presents a stage known as *sympathetic irritation*; it is very important to recognize this stage, since removal of the exciting eye at this period will prevent the progression of the affection from irritation to actual inflammation.

The Symptoms of Sympathetic Irritation.—The *sympathizing eye* is “*irritable*”; there are marked *photophobia* and *lacrymation*; neuralgic *pain* in the eye and neighboring parts; *dimness* of vision occurs when the eyes are used for near work; there may be *bright* and colored *sensations*.

The *exciting eye* usually presents an *iridocyclitis* or *uveitis*, which may be slight or severe; when the sympathizing eye becomes affected, there may be symptoms of irritation and marked tenderness over the ciliary region in the exciting eye.

These symptoms of irritation in the sympathizing eye may be *intermittent*; each attack may last a number of days or weeks, then subside, and recur a number of times. They may finally disappear entirely. But, as a rule, if the exciting eye is not excised *sympathetic inflammation results*.

The Symptoms of Sympathetic Inflammation.—These may follow directly upon those of irritation, or may occur after the sympathizing eye has been quiet for a time. They may begin *acutely* or *insidiously*. When once established the inflammation is *chronic*, and its duration is months or even one or two years. In the majority of cases *blindness* results, though occasionally, if the inflammation be mild, useful vision may be preserved.

The symptoms are *photophobia*, *lacrymation*, *dimness* of vision, and *tenderness* in the ciliary region. There will be circumcorneal *injection*, punctate *deposits* upon Descemet’s membrane, *increased depth* of the anterior chamber, *contracted pupil*, and *increased tension*.

In mild cases the symptoms may not pass beyond those of

cyclitis or iridocyclitis; but usually they develop into a *plastic uveitis* including iris, ciliary body, and choroid, and giving the following signs: The *iris* is thickened, its color becomes changed, its markings are obliterated, and it presents new blood-vessels upon its surface; it is firmly bound down by numerous and extensive posterior *synechiæ*. The *plastic exudation* fills up the pupil and more or less of the anterior chamber, which becomes shallow. *Tension* is diminished. The choroid and retina participate in the plastic inflammation, the *vitreous* presents numerous *opacities*, and the *lens* becomes opaque. Finally, there is *detachment* of the *retina*, the eyeball *shrinks* and passes into the condition of *atrophy*.

Theories of Transmission.—The mode of transmission is not definitely known. The theories which have been propounded are: (1) *Infection* spreading through the sheath of the optic nerve of one side to the chiasm and sheath of the optic nerve of the other eye; (2) conveyance by *blood-vessels*; (3) irritation through ciliary and optic *nerves*; the first is considered the most probable explanation.

Treatment.—*Prophylactic treatment* is of the greatest importance, and refers to the *removal of the exciting eye* under the following circumstances: We should *enucleate the injured eye* if it be *sightless*, or its condition such (especially when the ciliary region is involved) that we cannot hope to preserve useful vision; this is particularly imperative if it is *irritable*, has *ciliary tenderness*, presents the signs of *iridocyclitis*, or contains a *foreign body* which cannot be extracted.

When, however, there is *useful vision in the injured eye*, or a good chance of obtaining fair sight in this eye, the question of enucleation is often a difficult one to decide, since symptoms of sympathetic irritation may appear and then subside, and yet sympathetic inflammation never develop. In such cases we are often justified in waiting, if the injured eye remain *quiet and free from inflammation*, providing we can keep such a patient *under constant observation*.

After sympathetic inflammation has made its appearance, enucleation of the injured eye has no effect upon the progress of the disease; and the exciting eye may ultimately possess

better vision than its sympathizing fellow. Hence, under such circumstances, the exciting eye should not be removed if it possesses vision; if blind and exhibiting signs of inflammation, it should be enucleated, since its presence may aggravate the condition in the sympathizing eye.

The treatment of the sympathetic ophthalmia itself consists in the use of *atropine* (unless this seems to aggravate the symptoms), *hot compresses*, absolute *rest*, *shaded room*, and *smoked coquilles*; *leeches* to the temple are sometimes of advantage. *Mercurialization* is frequently resorted to, either calomel internally or inunction of the oleate up to the point of salivation. Since the disease is of lengthy duration, the *general health* of the patient must be looked after.

Though the *prognosis is unfavorable* and most cases end in blindness, the treatment must be carried out rigidly and patiently; in some cases at least, especially if the inflammation be of the *serous* type, *fair vision* may ultimately be obtained.

PANOPHTHALMITIS.

An intense *purulent inflammation of the entire uveal tract*, which fills the eyeball with *pus*, and ends in *complete destruction* of this organ. It is due to *infection*. It resembles *purulent choroiditis* (which term is often employed as a synonym), but the inflammatory process is more extensive.

FIG. 169.—Phthisis Bulbi.

Etiology.—It is almost always due to *infected wounds* of the eyeball, whether accidental or as a result of operations. It may also result from infective *ulcers*, *metastasis* in pyæmia and puerperal septicæmia, *meningitis*, and cerebro-spinal meningitis, especially in children.

Symptoms (already described in connection with purulent

choroiditis, p. 157) are apt to be *acute* and *severe*. The disease is usually ushered in by a rise of temperature, *general febrile symptoms*, headache, and sometimes vomiting. There are severe *pain* in the eyeball, rapid *loss of sight*, intense ciliary and conjunctival *congestion*, marked *chemosis*, and *swelling* and redness of the *lids* (Fig. 153, Plate XI). The *iris* soon becomes involved, the anterior chamber and vitreous become filled with *pus*, the cornea is *clouded* and yellow (Fig. 154, Plate XI), and *tension* increased. There is infiltration of Tenon's capsule, followed by *exophthalmos* and limitation of the movements of the eyeball.

Pus usually *breaks* through the anterior portion of the sclera, after which the pain and other symptoms *subside*; in the course of several weeks the process has run its course, leaving a *shrunk*, *sightless eyeball* (phthisis bulbi, Fig. 169).

Prognosis is always *unfavorable*: sight is invariably lost. The condition does *not* cause sympathetic ophthalmia.

Treatment.—The indications are to *alleviate pain* by the use of *hot, moist compresses*, and to *incise the sclera* so as to allow the escape of pus. If the case is seen early, thorough and repeated *cauterization* of the focus of infection with the electro-cautery or the introduction of small rods of *iodoform* into the anterior chamber, or both measures combined, may possibly be of value. It is not considered advisable to enucleate in the inflammatory stage, on account of the danger of setting up purulent meningitis.

CHAPTER XIV.

INTRAOCULAR TUMORS.

Intraocular tumors are *rare*. Their recognition is, however, important, since early enucleation of the eyeball may save life. There are two varieties: (1) Sarcoma of the Choroid, and (2) Glioma of the Retina.

SARCOMA OF THE CHOROID.

This *malignant* growth usually occurs in *adults* between the ages of forty and sixty. It is always *primary*, *single*, and involves *one eye* only. It may be formed of spindle or of round cells, and is usually pigmented (*melano-sarcoma*). It forms a *rounded mass* which springs from the choroid, most commonly near the posterior pole, and advances toward the centre of the eyeball, pushing the retina before it (Fig. 170).

FIG. 170. — Sarcoma of the Choroid, with Detachment of the Retina.

Symptoms.—There are four stages.

In the *first or quiescent stage*, there will be a *defect in the field* and *diminution in sight* depending upon the exact seat of the tumor. With the ophthalmoscope a *yellowish, brown, or black mass* may be seen, over which retinal vessels can be traced, and behind these other *vessels* belonging to the tumor itself. But very frequently the *retina becomes detached* and thus obscures this picture. The anterior ciliary veins may be found dilated near the seat of the growth. This stage usually lasts from eighteen months to two years.

In the *second or irritative stage*, the tumor *enlarges* in size and gives rise to *pain* and other symptoms of inflammatory *glaucoma*.

In the *third or extraocular stage*, the tumor *bursts* through the globe and then *increases* very rapidly in size, and *ulcerates*. In most cases it perforates anteriorly, and a dark mass is seen. If it perforates posteriorly, exophthalmos results. It soon implicates *neighboring structures*, including the brain.

The *fourth stage* is distinguished by the occurrence of *metastases*, most frequently in the liver.

Differential Diagnosis.—Sarcoma of the choroid may be mistaken for *detachment of the retina*, *glaucoma*, or possibly *glioma* of the retina; the last, however, occurs only during the first years of life. Ordinary detachment of the retina usually occurs suddenly in a myopic eye, or after a blow, and tension is diminished. From primary glaucoma sarcoma of the choroid is distinguished by the fact that sight is involved before the inflammatory symptoms appear, there are no premonitory symptoms such as usually precede glaucoma, nor remissions in symptoms, one eye only is involved, and the characteristic field of glaucoma (nasal limitation) is not present.

Treatment.—*Enucleation* as soon as the diagnosis is established, cutting the optic nerve far back. It may be necessary to clear out the entire contents of the orbit. There is always danger of *local recurrence* and of *metastases* in internal organs. The affection is invariably fatal when not removed early, death taking place within five years.

GLIOMA OF THE RETINA.

A *malignant growth*, consisting of small cells with some soft basement substance and blood-vessels; it occurs in *children* under five, usually in *one eye*, at times in both, and occasionally in successive children of the same family.

Symptoms.—We distinguish three stages.

In the *first or quiescent stage* there are no inflammatory symptoms. The ophthalmoscope shows small *whitish or yellowish masses* with *metallic lustre*, growing into the vitreous; the surface presents *newly formed blood-vessels* and may also show hemorrhages and white patches. The attention of the parents is attracted by the striking *yellow reflex*, easily seen

through the pupil, which is usually in a condition of *dilatation*; this symptom has given rise to the synonym "*amaurotic cat's eye*."

In the *second or irritative stage* there are *pain*, increase of *tension*, and other symptoms of *glaucoma*. The tumor *increases* in size and extends into the vitreous. Very soon the growth can no longer be seen on account of *turbidity* of the media.

In the *third or extraocular stage* there is bulging of the eyeball, both *staphyloma* and *exophthalmos*, and then *perforation* takes place. The growth passes backward along the optic nerve to the *brain* (in this way it becomes fatal), and forward though the cornea and sclera, *increasing* in size rapidly and involving all tissues with which it comes in contact. *Metastases* are rather rare.

Differential Diagnosis.—We must distinguish glioma from *pseudo-glioma* (p. 157), the degenerated eyeball which is the outcome of purulent choroiditis following meningitis or cerebro-spinal meningitis in children. In the latter affection there will be the history of a previous acute febrile disease with inflammation of the eyeball, and tension is diminished; with the ophthalmoscope we fail to see the irregular curved surface covered by newly formed vessels, and there are signs of previous inflammation of the iris. When in doubt, such eyes being always sightless, we should *enucleate*.

Treatment.—*Enucleation* as soon as possible, cutting the optic nerve far back. If the growth has perforated, the entire orbit must be cleaned out; even then there is danger of *recurrence*. When excision is practised early there is a fair chance of cure. Unless this is done death occurs within two or three years.

CHAPTER XV.

GLAUCOMA.

Anatomy.—The *aqueous chamber* is bounded in front by the cornea, behind by the lens and its suspensory ligament, and laterally by the ligamentum pectinatum and anterior portion of the ciliary body (Fig. 171). Its depth varies; it is comparatively deep in the young, in myopic eyes, and when the eye is focussed for distant objects. The iris divides the aqueous cavity into an *anterior* and a *posterior chamber* (Fig. 172). The former lies in front of the iris. The latter is the annular space between the iris and the lens; since the iris is in contact with the lens only at its pupillary margin, this space increases in depth from the pupil to the peripheral border of the iris, and is triangular in cross-section. The posterior communicates with the anterior chamber by means of the pupil.

The portion of the anterior chamber where the sclerocorneal margin, iris, and ligamentum pectinatum meet is known as the *angle* or *sinus of the anterior chamber* (often called the *iris angle*). This region is of *great importance*; upon its integrity depends the proper circulation of the lymph which nourishes the anterior portion of the eyeball.

The *ligamentum pectinatum* is formed by the breaking up of Descemet's membrane at the margin of the cornea, into bundles which connect the sclera with the root of the iris. These elastic laminae are covered by endothelium continued from Descemet's membrane. In this way spaces are formed which are continuous with the cavity of the aqueous, are lined with endothelium, and are known as the *spaces of Fontana*. To their outer side, at the sclerocorneal junction, is *Schlemm's canal*, a plexus of veins.

With the exception of the conjunctiva, no portion of the eyeball contains lymphatic vessels; in place of such vessels and serving the same function, there are *lymph channels* and *lymph spaces*. These may

FIG. 171.—Section of the Eyeball at the Sclero-corneal Junction, Showing Angle of Anterior Chamber. S, Sclera; C, cornea; I, iris; L, lens; cm, ciliary muscle; Sch, canal of Schlemm.

be divided into those of the anterior and those of the posterior portion of the eyeball.

The *anterior lymph spaces and cavities* consist of the aqueous chamber and the parts immediately around the iris angle. The anterior and posterior chambers represent two large lymph spaces which collect the lymph of the anterior portion of the eye. This lymph is known as the *aqueous humor*, and consists of a clear, watery fluid, secreted by the epithelium covering the ciliary processes and the posterior surface of the iris. It first passes into the posterior chamber, then through the pupil into the anterior chamber, and leaves the eye through the spaces of the ligamentum pectinatum (Fontana's spaces) and Schlemm's canal, passing into the anterior ciliary veins; a portion passes into the lymph spaces of the iris, and thence to the suprachoroidal lymph space.

FIG. 172.—Diagrammatic Section of the Anterior Portion of the Eyeball showing: (1) Upper Conjunctival Sac, (2) Lower Conjunctival Sac, (3) Anterior Chamber, (4) Posterior Chamber.

The *posterior lymph passages* consist of the hyaloid canal of the vitreous, and of the suprachoroidal space (between choroid and sclera), communicating with Tenon's space along the *venæ vorticosæ*; both have for an outlet the

supravaginal and infravaginal spaces of the optic nerve.

GLAUCOMA.

Glaucoma is an *important* and *common* disease of the eye, which has for its characteristic sign an *increase of intraocular tension*.

Varieties.—It is (1) *primary*, when occurring without antecedent ocular disease, and (2) *secondary*, when it follows as a result of some pre-existing disease of the eye.

Primary Glaucoma occurs under two forms: 1, *Inflammatory* or *Congestive*, and 2, *Non-inflammatory* or *Non-congestive*, usually spoken of as *Simple*.

The *inflammatory* variety is again divided into 1, *acute*, and 2, *chronic*.

These variations in clinical types of primary glaucoma are explained by the rapidity with which the increase of intra-

ocular pressure shows itself and the height to which it rises. When the increase of tension is rapid, the *inflammatory* type results; when gradual, the eyeball accommodates itself to a certain extent to the altered conditions, and symptoms of inflammation or congestion are absent or only very slightly marked; the disease is then known as *simple* glaucoma (non-inflammatory or non-congestive glaucoma); this type is always chronic in its course.

All forms of glaucoma present very characteristic *remissions* or *intermissions* in the course of the disease.

ACUTE INFLAMMATORY GLAUCOMA.

Inflammatory glaucoma presents a clinical picture which *varies with the type of disease*, depending upon the suddenness of onset, duration, and the presence or absence of congestive signs—hence the classification into *acute* and *chronic* inflammatory cases; intermediate cases are sometimes described as *subacute*.

Symptoms.—The affection can be divided into *three stages*: 1, the *prodromal* stage, 2, the stage of *active glaucoma*, and 3, the stage of *absolute glaucoma*. To these we may add a fourth stage, the stage of *degeneration*.

The Prodromal Stage.—This stage is present in most instances; it may, however, be absent. There will be some *diminution in the acuteness of vision*—the sight appears to be obscured by *fog*. A ring of *rainbow tints* will be seen around lights; the *cornea*, especially at its centre, will, upon careful inspection, be found slightly *clouded*; this condition (œdema) is the cause of the preceding symptoms. There will be a feeling of dulness or *slight pain* in the eye and head. The *anterior chamber* is rather *shallow*, the *pupil* somewhat *dilated*, often oval, and *sluggish* in reaction. The *tension* of the globe is *increased*. There is often slight circumcorneal *injection*.

These symptoms last for a number of hours and then disappear entirely; the eye returns to a normal condition, except that there is a *diminution in the power of accommodation*, so that the patient requires stronger glasses than are natural at his age. Hence a rapid increase of presbyopia should always ex-

cite suspicion of glaucoma. Such prodromal attacks are often excited by insomnia, worry, dissipation, insufficient food, some condition which causes venous congestion, and sometimes by a hearty meal, indigestion, or the local use of *atropine*. They are in many cases relieved by sleep. At first the attacks are separated by *intervals* of weeks or months, but they soon become more frequent.

This stage lasts a number of weeks or months, sometimes several years; then the disease suddenly passes into the second stage.

The Stage of Active Glaucoma.—The *sudden onset* which characterizes this stage may be due to one of the exciting causes which bring on the prodromal attacks. There are rapid *failure of sight*, *contraction of the visual field* especially on the nasal side (Fig. 175), and severe *pain in the eye*, radiating along the branches of the fifth nerve and causing violent *headache*; this pain is sometimes so severe that it occasions nausea, vomiting, general depression, and febrile disturbances, such attacks having been mistaken for “bilious attacks.”

Objective examination reveals marked *increase in tension*. The *lids* are *swollen* and *œdematous*. The *ocular conjunctiva* is markedly *congested* and *chemotic*.

The *cornea* is clouded or *steamy* (due to œdema), often presents punctate opacities, and is *insensitive* (from pressure upon nerve filaments); there is pronounced *circumcorneal injection* of a dark red color; the *episcleral veins* are *prominent* (Fig. 173, Plate XV). The *anterior chamber* is *shallow*, the aqueous sometimes turbid. The *pupil* is *dilated*, *oval*, *immobile*, and often presents a greenish re-

FIG. 175.—The Field of Vision in Glaucoma (Left Eye). Peripheral Contraction, especially on the Nasal Side.

flex. The *iris* is congested, *discolored*, and *dull*. The lens and the periphery of the iris are pushed forward. No details of the fundus can be seen with the ophthalmoscope, on account of the *clouding of the media*.

PLATE XV.

FIG. 173.—Acute Inflammatory Glaucoma.

FIG. 174.—The Fundus in Chronic Glaucoma.

In many cases in the course of a few days or weeks a *decided improvement* takes place. The pain subsides, congestion and oedema of lids and conjunctiva disappear, the cornea clears up, and sight improves. But the eye does not return to a perfectly normal condition; it is left in a condition known as the

Glaucomatous State.—Vision is not so acute as it was before the attack, and the visual field is somewhat contracted especially on the nasal side. The pupil remains dilated, oval, and sluggish, the iris discolored, the anterior chamber shallow,

FIG. 176.

FIG. 177.

FIG. 178.

FIGS. 176, 177, 178.—Ophthalmoscopic Appearances and Longitudinal Section of the Optic-Nerve Disc. FIG. 176, Normal Disc; FIG. 177, Disc in Optic-Nerve Atrophy; FIG. 178, Glaucomatous Excavation.

tension increased, and there is more or less circumcorneal injection; the power of accommodation is diminished.

After a period of quiescence of variable length, *another attack* occurs similar to the first, and this is succeeded by others; each attack causes greater reduction in sight.

After a while, the increased tension causes *excavation of the optic-nerve disc* (Fig. 178) recognizable with the ophthalmoscope in the intervals between attacks, when the media are clear. The lamina cribrosa, the portion of the sclera which is perforated by the optic-nerve fibres, is most yielding and hence bulges backward with the fibres of the nerve as a result of increased intraocular pressure. With the ophthalmoscope a *deep depression* with very steep or *overhanging margins* is seen; this is known as the *glaucomatous cup or excavation*

(Fig. 174, Plate XV). The *blood-vessels bend* sharply over the margins of this excavation and often appear *interrupted* in this situation, being again seen, more or less faintly, at the bottom of the depression. They are pushed over toward the nasal side. The veins are distended and the arteries contracted. There is *pulsation* in the veins and in the *arteries* at the disc. Pulsation in the veins is often seen in health, but arterial pulsation is always pathological, and is an important symptom of glaucoma (it is also seen in certain forms of heart disease); if not spontaneous, it can be produced by slight pressure upon the eyeball. The *optic nerve* becomes *atrophied* and the disc appears *pale*, or in late stages *greenish* or bluish. The disc is often surrounded by a whitish-yellow ring (*glaucomatous halo or ring*), due to atrophy of the choroid in this situation.

The Stage of Absolute Glaucoma.—With each succeeding attack the diminution in vision becomes greater, until finally *blindness* ensues; the condition is then known as *absolute glaucoma*. There are now no inflammatory or congestive symptoms, except a dark-red zone of *circumcorneal injection* and *dilated episcleral veins*. The cornea remains clear or slightly clouded, and often more or less insensitive. The *pupil* is widely *dilated*, *immobile*, and often presents a *greenish* reflex. The *iris* is *atrophied*, narrow, gray, with a border of dark pigment. The *anterior chamber* is *shallow*. *Tension* is markedly *increased*. The fundus presents a *deep excavation of the disc*, the glaucomatous ring, and atrophy of the optic nerve. *Pain* may disappear entirely, but frequently continues, and the patient suffers from severe attacks at intervals.

The Stage of Degeneration.—After absolute glaucoma has lasted a variable length of time, the eyeball is apt to degenerate. The *cornea* becomes more or less *opaque*, and frequently covered by deposits or vesicles. The *sclera* *bulges* and bluish-black staphylomata appear between the cornea and the equator. *Detachment of the retina* often takes place. The *lens* is apt to become *cataractous*. The patient may experience subjective sensations of light. The final result is that the *eyeball* either softens, shrinks, and *atrophies*, or else there are

ulceration and perforation of the cornea, followed by iridocyclitis, with subsequent atrophy of the eyeball, or panophthalmitis and phthisis bulbi.

Glaucoma Fulminans is the name given to a form, of rare occurrence, in which very violent symptoms of inflammation develop suddenly, and in which blindness may ensue in a few hours, unless proper treatment be instituted.

CHRONIC INFLAMMATORY GLAUCOMA.

This form of glaucoma is much *more common* than the acute variety just described. *Its symptoms resemble those of the acute variety, but are less intense and more gradual in their onset.* Very often the prodromal stage passes uninterruptedly into the stage of active glaucoma, and there is no succession of attacks. The ocular conjunctiva is congested and dusky, the episcleral veins being very prominent; there is circumcorneal injection of a dark-red color; the cornea is steamy and more or less insensitive; the anterior chamber is shallow, and the lens and iris are pushed forward; the pupil is dilated, oval, and rigid, surrounded by the discolored, narrow, and atrophic iris, and presents a greenish reflex. There is pain, but this is not so intense as in the acute form. There are gradual loss of sight and progressive limitation of the field, especially on the nasal side. After having lasted a sufficient length of time, the ophthalmoscope reveals the same changes in the fundus which are found in acute cases.

The chronic form has the same termination as the acute: absolute glaucoma and finally degeneration of the eyeball. In many cases, no sharp line of differentiation can be drawn between the acute and the chronic forms of inflammatory glaucoma.

SIMPLE GLAUCOMA.

In simple glaucoma (*Chronic Non-Inflammatory Glaucoma*), there is an *absence of any marked external symptoms*; there are *no inflammatory attacks and no pain*.

The diagnosis is made by noting the *increase of tension*, and by the picture presented when the *ophthalmoscope* is used.

This form develops very *gradually*, and may have lasted some time before the patient becomes aware of the existence of any abnormal condition. The eye may appear perfectly normal externally, or there may be *slight circumcorneal injection* and *moderate dilatation* of the *episcleral veins*. The *pupil* is slightly or *moderately dilated* and is *sluggish*. The *tension* is *elevated*, often moderately; sometimes the increase is not constant. After the disease has lasted a certain length of time, the ophthalmoscope shows *glaucomatous excavation* (Fig. 178, and Fig. 174, Plate XV), atrophy of the optic nerve, and the circumpapillary ring of choroidal atrophy, the degree of change depending upon the duration of the process.

There may be periods when the patient complains of symptoms like those in the prodromal stage: *Foggy vision*, *colored halos* around artificial lights, and *diminished accommodation*. There are *gradual loss of sight*, *premature presbyopia*, and *progressive contraction* of the *visual field*, especially on the nasal side. Central vision is the last portion to be lost. On this account the patient may be able to read, and yet the field of vision be quite limited.

The *course* of simple glaucoma is very *insidious* and its *duration* is *years*; if unchecked, it terminates in *blindness*. Sometimes this form gradually changes into the chronic inflammatory type, and then goes through the stages of the latter disease.

Occurrence and Etiology.—Glaucoma is a disease of *advanced life*, occurring generally between fifty and seventy, infrequently before this period. The inflammatory form attacks women more often than men, the simple type occurs equally in both sexes. It usually involves *both eyes*, the second eye generally becoming affected months or years after the first. The exact cause of glaucoma is unknown. There are a number of *predisposing conditions*: It occurs much more frequently in Jews than among Christians. There is not uncommonly a history of *heredity*. *Arteriosclerosis* and cardiac disease, chronic constipation, and the *gouty* and *rheumatic* diatheses are predisposing factors. A disposition toward in-

inflammatory glaucoma exists in *hyperopic eyes* (myopic eyes are particularly exempt) as well as in small eyeballs, and in those in which the cornea is of small size. The *exciting causes* may be the following: *Emotions* especially of a depressing character, *insomnia*, *worry*, injudicious use of *atropine*, *overuse* of ametropic eyes, insufficient food, indigestion, dissipation, various fevers especially influenza, and any condition which produces *venous congestion*.

Pathology.—All the symptoms of glaucoma can be explained by the *increase in intraocular pressure* and the resulting *venous congestion*. But the cause of this increase in tension has not yet been determined; none of the *many theories* has been adequate to explain the occurrence of this disease in every case. The increased tension must depend upon a *disturbed relationship between intraocular secretion and excretion*.

The older theories assumed the existence of *hypersecretion* produced in various ways; these views have been discarded. It is at the present time considered more probable that the disease is due to some interference with excretion (*retention*). The ob-

struction to the escape of the intraocular liquids is thought to be situated at the *angle of the anterior chamber* (iris angle). It is believed that this angle (Figs. 171, 179, 180) is *obliterated* by pressure of the peripheral portion of the iris against the sclerocorneal junction (ligamentum pectinatum) by the congested and swollen ciliary processes, with or without *adhesive inflammation* between the opposed surfaces. As already explained, this iris angle forms the principal exit for intraocular fluids, and when it is blocked up, retention takes place. An additional causative factor is supposed to be the *narrowing of*

FIG. 179.—Angle of the Anterior Chamber in the Normal Eye.

FIG. 180.—Angle of the Anterior Chamber in Recent Inflammatory Glaucoma.

the space between the margin of the lens and the ciliary body in eyes predisposed to glaucoma. This area serves for the passage of the lymph which is secreted by the choroid and part of that produced by the ciliary body. The circumlental space is encroached upon by the increased size of the lens with advancing age, by the comparatively large size of the ciliary body and the smaller size of the eyeball in general, in *hyperopes*. This embarrassment in the communication between vitreous and aqueous chambers would cause venous congestion, subsequent swelling of the ciliary body, overdistention of the vitreous, with the result of pushing the periphery of the iris against the sclerocorneal junction, thus blocking up the iris angle. But no explanation of the production of glaucoma satisfactorily fits all types of the disease.

Differential Diagnosis.—The *inflammatory form* of glaucoma has been mistaken for *iritis* and *conjunctivitis*; the use of atropine in such cases has caused great mischief. The dilated pupil, increase in tension, turbidity of cornea, as well as the subjective symptoms ought to be sufficient to differentiate (see tables on p. 141). The peculiar greenish pupillary reflex has been diagnosed as *cataract*, and thus valuable time has been lost in awaiting the ripening of this supposed lens change. In acute cases, the violent headache and general constitutional symptoms have misled the medical practitioner, and been responsible for the diagnosis of some *general febrile disease*, at a time when active ocular treatment was urgent.

Simple glaucoma is sometimes mistaken for *simple optic-nerve atrophy*. In the latter case, there will be absence of increased tension, the excavation of the disc is shallow and gradual (Fig. 177 and Plates XV and XX), there is apt to be greater diminution in central vision, the form fields present more uniform contraction, and the color fields show greater peripheric loss. There are, however, instances in which the differential diagnosis between these two affections is not easy.

Prognosis is *bad* in every case, *if proper treatment is not instituted*; vision becomes worse, more or less rapidly, but progressively, until complete *blindness* results. *With correct treatment the prognosis is more favorable.*

Treatment.—(1) *Operative*, (2) *medicinal*, and (3) *general*. The most efficient treatment is *iridectomy*.

Non-Operative Treatment consists chiefly in the local use of the *miotics*—*eserine salicylate* ($\frac{1}{3}$ to $\frac{1}{2}$ per cent.), and *pilocarpine muriate* (one per cent.). The former has the stronger action, but produces more conjunctival irritation and ciliary congestion when used for a long time. These solutions are instilled two or three times a day or oftener; they act by drawing the iris away from the angle of the anterior chamber; hence, they are of no value after the iris has become atrophic and is incapable of contracting, a condition observed in old cases of glaucoma. They are merely *palliative* measures, often proving only of *temporary* advantage. They may be used in the *prodromal stage* to cut short the attack, or at other times, if for any reason *iridectomy* cannot be performed, or the patient refuses to allow an operation to be done. They are also useful in *acute inflammatory attacks* to alleviate pain, reduce tension, diminish cloudiness of the media and increase the depth of the anterior chamber, thus rendering *iridectomy* easier of execution.

Massage of the eyeball, applied gently to the closed lids, for a few minutes each day, is sometimes used with advantage.

General Treatment comprises rest, proper and sufficient food, salicylate of sodium, anti-rheumatic remedies, relief of constipation, correction of ametropia, avoidance of excess in eating, drinking, and late hours, the induction of sleep, and the relief of any of the other conditions which have been mentioned as predisposing to glaucoma.

Operative Treatment consists of *iridectomy*, the excision of a portion of the iris, and *sclerotomy*, an incision through the sclera.

Iridectomy.—*The Instruments Required* include an eye speculum (Fig. 181), a fixation forceps (Fig. 182), a bent and a straight lance-shaped knife (Figs. 183 and 184) or a Graefe cataract knife (Fig. 185), a curved iris forceps (Fig. 186) or a Matthieu iris forceps (Fig. 187), curved iris scissors (Fig. 188) or De Wecker's iris scissors (Fig. 189), a metal spatula and probe (Fig. 190), and a blunt iris hook (Fig. 191).

The operation will be described as done for glaucoma. *Cocaine* or *holocain* may be employed in simple glaucoma and in many cases of inflammatory glaucoma; but in nervous and unruly individuals, as well as in some instances of the inflammatory forms of glaucoma, complete *general anæsthesia* is necessary, since the tense and congested tissues do not readily absorb local anæsthetics, and the seizing and cutting of the iris is painful. Solution of *adrenalin chloride* (1:1,000) used in connection with cocaine or holocain may produce a more satisfactory anæsthesia; a few drops of a four-per-cent. solution of cocaine injected subconjunctivally, just below the cornea, also increases the depth of the local anæsthesia.

Operation.—Iridectomy for glaucoma is usually done *upward*, so that the defect is covered by the upper lid, thus limiting troublesome optical effects of the coloboma. The operator,

FIG. 192.—Section of the Sclera in Iridectomy.

FIG. 193.—Division of the Iris in Iridectomy.

standing behind the patient's head, introduces the speculum, obtains a firm grasp of the conjunctiva just below the lower margin of the cornea, directs the patient to look down, and thrusts the lance-shaped knife into the sclera above the cornea, entering 1 mm. behind the limbus (Fig. 192); the knife is directed perpendicularly until its point is seen in the anterior chamber, and then pushed forward in a direction parallel to the plane of the iris until the scleral wound is of sufficient

FIG. 190.—Knapp's Probe and Spatula.

size (6 to 8 mm.); care is taken not to pass between the layers of the cornea, nor to wound the iris or lens capsule. The knife should be *withdrawn slowly* so that the reduction in tension is not too sudden, which might cause intraocular hemorrhage and other injury; its point is directed toward the cornea without scraping its posterior surface. When there are considerable increase in tension and a very shallow anterior chamber, the Graefe knife is sometimes preferred for the scleral incision. It is made to enter 1 mm. behind the limbus, at about the junction of the lower five-sixths with the upper sixth, passes across the anterior chamber (great care being exercised not to wound the iris or lens capsule), and emerges at a corresponding point 1 mm. behind the limbus on the opposite side, the incision being completed by to-and-fro movements.

An assistant now takes the fixation forceps. The operator passes the closed iris forceps through the scleral incision to the pupillary margin, opens the instrument, seizes the pupillary border of the iris between its branches, draws the iris out of the wound, and cuts it off close to the cornea, the blades of the iris scissors being parallel to the wound (Fig. 193). This can be done either with one cut, or with two or three cuts; in the latter case, the first stroke divides the iris at one corner,

FIG. 194.

FIG. 195.

FIG. 196.

FIG. 194.—Iridectomy in Glaucoma. FIG. 195.—Iridectomy Preceding Cataract Extraction. FIG. 196.—Iridectomy for Artificial Pupil.

the second the central part (or this portion may be loosened by tearing), and the third the iris at the other corner of the wound. The piece of iris removed should be at

least one-fifth of the entire circle (Fig. 194), and should comprise the entire width including the ciliary attachment.

In iridectomy performed on an aphakial eye (after cataract operations), it is difficult to grasp the iris with forceps; in such cases the iris is drawn out with the blunt hook (Fig. 191).

The resulting *coloboma* must be large, cleanly cut, and the

pupillary margin of the iris must return to its natural position producing a *keyhole-shaped pupil* (Fig. 194). No iris tissue must be left in the wound, since this causes subsequent irritation and complications. Proper replacement of the iris is accomplished by stroking the wound with a spatula, or, if this is unsuccessful, by passing the spatula into the incision and freeing the angles.

Hemorrhage into the anterior chamber is common; the blood is usually absorbed in a few days; it is not wise to make too great efforts to dislodge the blood, since undue pressure may cause the lens to become cataractous.

Both eyes are bandaged, and the patient is kept quiet in bed. After two days, the unoperated eye may be left uncovered. Recovery is smooth in most instances; in some cases the anterior chamber is not re-formed for several days. Cystoid cicatrix sometimes results—a condition which is not objectionable and is thought to facilitate filtration.

Results of Iridectomy in Glaucoma.—The manner in which iridectomy relieves glaucoma is not definitely known. The *earlier* the operation is performed, the more sight is preserved. Hence it is advisable to do the operation *as soon as possible*. The best time is during the prodromal stage, in the interval between attacks. In inflammatory cases, during the stage of acute glaucoma, the operation is very difficult on account of the severe congestion and the shallowness of the anterior chamber; under such circumstances, it is usually advisable to instil eserine or pilocarpine at frequent intervals for a day or two, so as to reduce tension and increase the depth of the anterior chamber, and then to operate; but if these miotics do not act, the operation must be performed without further delay.

The most favorable results of iridectomy are seen in cases of *acute inflammatory glaucoma*; in such instances pain and inflammatory symptoms subside rapidly and sight returns up to the degree possessed before the onset of the attack. Furthermore, the results are generally *lasting*. Exceptionally the effects of an iridectomy are disappointing or *temporary*, and the operation must be repeated opposite to or at the

side of the first, or sclerotomy performed. In rare cases operation has no effect upon the course of acute inflammatory glaucoma, and the disease progresses until blindness ensues.

In chronic inflammatory glaucoma, the results of iridectomy are *favorable*, but not so brilliant as in acute cases. The operation relieves the pain and inflammatory symptoms, and the media again become clear; but since the disease has already caused permanent changes in the disc and optic nerve, the restoration of sight is limited. But the *progress of the disease is generally checked*, though sometimes a second operation must be performed. In a certain number of cases, however, there is progressive diminution in sight notwithstanding the operative intervention.

In simple glaucoma iridectomy is also indicated, but its results are *less marked and less permanent* than in the inflammatory variety. The most that we can expect from the operation is that the acuteness of vision prevailing at that time will be preserved or slightly increased, and that the *progress of the disease will be arrested*. This happens in about one-half the cases. In the other half the results are not so favorable. In some of these, the effects of the operation are only *temporary* and the iridectomy has to be repeated; in others, the *disease progresses* after a shorter or longer interval of arrest, and blindness finally ensues. In a very small proportion, the operation has an unfavorable effect upon the disease; violent inflammatory symptoms appear immediately after the operation and the eye rapidly becomes blind; such cases are known as *malignant glaucoma*.

In *absolute glaucoma*, *enucleation* is often indicated for the relief of severe pain.

Indications for Iridectomy.—Besides (1) glaucoma, the operation is indicated in (2) some cases of chronic and recurrent iritis and iridocyclitis; (3) complete circular synechia; (4) partial corneal staphyloma; (5) tumors and foreign bodies in the iris; (6) recent prolapse of the iris; (7) as a part of the operation of extraction of cataract—here the coloboma should be smaller than in glaucoma (Fig. 195); (8) as a means of im-

proving sight (artificial pupil, optical iridectomy) in central opacities of the cornea and lens, occlusion of the pupil, and keratoconus.

Optical Iridectomy: A small incision (3 to 4 mm.) is made in the cornea, 2 mm. from the limbus, the iris drawn out with a Mathieu forceps (Fig. 187) or the blunt hook (Fig. 191), and its pupillary portion excised, making as *small* a coloboma as is practicable (Fig. 196). The best position for the artificial pupil is *downward and inward*; but when there is a corneal opacity, the site must correspond to the most transparent portion of the cornea. The effects of optical iridectomy are often disappointing; hence, before operating, it is well to dilate the pupil and, by applying a stenopæic slit held in different positions, to ascertain whether there is an improvement in sight under these circumstances.

Sclerotomy (*Incision Through the Sclera*) is sometimes performed for the cure of glaucoma, but it is considered *inferior to iridectomy*. It may, however, be a useful procedure in cases in which iridectomy cannot be satisfactorily performed, or in which a relapse occurs after iridectomy has been done once or twice. The incision in the sclera is made in two situations: in front of the iris (anterior sclerotomy), and behind the ciliary body (posterior sclerotomy).

Anterior Sclerotomy: An incision is made with a Graefe knife, 1 mm. behind the limbus, similar to that made in iridectomy, but the middle third is left uncut and forms a bridge connecting sclera and cornea.

Posterior Sclerotomy: An incision (1 mm. deep) is made through the sclera into the vitreous with a Graefe knife. The site usually selected is between the external and inferior recti muscles; the cut must not approach the cornea nearer than 7 mm., so as to avoid endangering the ciliary body. This operation is also performed in detachment of the retina (in which case the puncture is made over the separation), and as a preliminary step in the removal of foreign bodies from the vitreous.

Exsection of the Superior Cervical Ganglion of the Sympathetic has been performed many times during the past few

years; the results have not been brilliant; the operation may possibly be of value when all other measures seem inadvisable or have failed.

Secondary Glaucoma is the name given to those cases in which increased tension and other symptoms of glaucoma are developed as a result of some other ocular disease or injury. The clinical picture varies with the disease which it complicates. The consequences are the same as in primary glaucoma.

The ocular affections which are most frequently followed by secondary glaucoma are: Ulcers or wounds of the cornea with prolapse of iris, corneal cicatrices and staphylomata with incarceration of the iris, iridocyclitis, uveitis, choroiditis and myopia of high degree, total posterior (ring) synechia, dislocation of the lens, traumatic cataract (swelling of the lens), the operations of extraction, needling of the lens and discission of secondary cataract, intraocular tumors, and foreign bodies in the eye. In old persons with arteriosclerosis, a form of secondary glaucoma with retinal hemorrhages is seen, and is known as *hemorrhagic glaucoma*.

The *treatment* depends upon the primary disease. We endeavor, if possible, to *remove the cause*. *Hemorrhagic glaucoma* does not respond favorably to treatment; iridectomy is liable to be followed by an aggravation of symptoms; the other agents used in glaucoma may be tried, but are usually of no benefit.

Congenital Glaucoma (*Hydrophthalmos, Buphthalmos*) is a disease of *early childhood*, either congenital or developing in infancy and usually involving *both eyes*. There is an *increase of intraocular tension* which, on account of the yielding character of the sclera at this period of life, causes *marked enlargement of the eyeball*. The cornea is enlarged and bulging, and either remains clear or becomes clouded; the anterior chamber is very deep; the pupil is dilated, and the iris atrophied and tremulous; the sclera is thinned and bluish, owing to the uveal pigment showing through; the disc is deeply excavated. The disease *progresses slowly*. Though in some cases it comes to a spontaneous stop with the preservation of

moderately good vision, it generally leads to *blindness*. The *prognosis* is *unfavorable*. As a rule *treatment* is of no avail; since, however, a few cases have been benefited by iridectomy, sclerotomy, repeated paracentesis of the anterior chamber, and miotics, these measures should be tried.

CHAPTER XVI.

DISEASES OF THE VITREOUS.

Anatomy.—The vitreous is a *transparent*, colorless mass, of soft *gelatinous* consistence, which fills the posterior cavity of the eyeball behind the lens. Its outer surface presents a thin, structureless covering, the *hyaloid membrane*. The vitreous is traversed from the optic disc to the posterior capsule of the lens by a canal, the *hyaloid canal*, serving as a lymph channel in the developed eye, and containing the hyaloid artery during foetal life. In structure the vitreous consists of a *transparent network*, in the meshes of which are *clear liquid* and round and branching *cells*, probably emigrated white blood-corpuscles. The vitreous has no blood-vessels, but receives its nourishment from the surrounding tissues, the choroid, ciliary body, and retina.

Persistent Hyaloid Artery.—The hyaloid artery usually disappears entirely during the later months of gestation. Occasionally a greater or lesser remnant persists during life. This can be seen with the ophthalmoscope, as a *grayish cord or thread*, which arises from the optic disc and stretches into the vitreous, with a free extremity or occasionally attached to the posterior pole of the lens. Rarely, the hyaloid canal is abnormally dense and is visible as a grayish, tubular cord extending from disc to lens.

Muscae Volitantes is the term employed for the appearance of *spots* before the eyes, *without appreciable structural change* in the vitreous or other media. They are caused by the shadows cast upon the retina by the cells normally found in the vitreous, and are present in all eyes under certain circumstances, such as exposure to a uniform bright surface, or in looking through a microscope. They are found more frequently in *errors of refraction* (especially *myopia*), and temporarily during *digestive derangements*. They occur as grayish shadows, which move with changes in the position of the eyes, having the shape of dots or globules, frequently collected into strings; they may have any shape. They are *annoying* and sometimes alarm the patient, but are of *no importance*, and do not affect the acuteness of vision. The *treatment* consists in

correcting any error of refraction, or in relieving the disturbance of digestion. They often persist until the patient ceases to look for them and thus forgets their existence.

Opacities of the Vitreous are quite common. They may occur as a consequence of *changes in the vitreous itself*, but usually they are the result of disease or of hemorrhages from the *neighboring structures*—ciliary body, choroid, and retina. They vary in number, shape, and size:

(1) A *diffuse cloud or a dust-like haziness* often accompanies cyclitis, choroiditis, iridochoroiditis, and retinitis; when dust-like it is suggestive of syphilitic choroidoretinitis and iridocyclitis.

(2) The opacities may occur in the form of dots, flakes, threads, or membranous masses, the result of *exudations* or *hemorrhages*.

(3) Sometimes extensive *membranes* are met with, which are attached to the retina and provided with blood-vessels; these are supposed to result from chronic retinal disease, called *Retinitis Proliferans*.

(4) Occasionally small glistening opacities are found in degenerated eyeballs and in some which are normal in other respects, especially in old persons; they fall in a silvery shower when the eyeball is moved; they are usually crystals of cholesterin in a fluid vitreous; the appearance is known as *Synchysis Scintillans*.

Symptoms.—There is more or less *disturbance of vision*, depending upon the situation, size, and density of the opacities. The *opacities* are most frequently *movable*, indicating a fluid vitreous (*synchysis*), the result of disease of surrounding parts. On this account, the visual disturbance may vary according to the part of the vitreous occupied by the opacity, and the patient may be able to move the eyeball in a certain way so as to throw the opacity out of the line of sight. *Fluid vitreous* gives rise to diminished tension, often a tremulous condition of the iris, and may predispose to detachment of the retina.

Diagnosis is made with the *ophthalmoscope at a distance*. The vitreous opacities appear as *dark spots* upon a red

ground, when the eye is moved in various directions. When faint, the opacities are best seen with *diminished illumination* and with the plane mirror.

Prognosis *varies* with the size, density, and nature of the opacity. Syphilitic opacities and small hemorrhages frequently clear up when treated early. Others become smaller and less dense after a time. A great many are permanent.

Treatment.—*Anti-syphilitic* treatment is indicated in specific cases. In others, small doses of *potassium iodide* and *mercury* may be of service. Diaphoretics and cathartics are sometimes employed. *Subconjunctival injections* of physiological salt solution (0.6 per cent.) may be useful.

Hemorrhages into the Vitreous usually come from the *choroidal vessels* and produce *opacities* of small or large size, causing the symptoms of opacities of the vitreous. When *small*, they have a *red color* as seen with the ophthalmoscope; when *large*, no red reflex can be obtained and the *pupil* appears *black*. The smaller hemorrhages are often absorbed; the larger ones frequently leave dense membranous masses. They occur after injuries, after operations upon the globe, in *choroiditis*, *myopia* of high degree, and retinitis; they are not uncommon in old persons with atheromatous arteries. Sometimes they are found in the young without discoverable cause, and in such cases they may recur repeatedly. The exciting cause is often a strain of some sort, such as a cough. *Treatment* consists in absolute rest, bandage to the eyes, treatment of any accompanying ocular affection, or of the general condition.

Foreign Bodies in the Vitreous.—The entrance and lodgment of a foreign body (wood, glass, or metal) within the globe usually causes *severe inflammation* and *destruction* of the eyeball as a result of iridocyclitis or panophthalmitis unless the substance be promptly extracted; the gravity of the accident depends upon the nature of the foreign body and the presence or absence of *infection*. Occasionally these substances remain quiescent and become encysted; but even in such cases there is danger of subsequent inflammation.

The presence of a particle of iron for any length of time is

apt to cause a rusty-brown or greenish discoloration of the iris and lens, known as *siderosis*.

Diagnosis.—If the patient comes under observation soon after the injury, before the media have become hazy, we may be able to see the particle with the *ophthalmoscope*; and a careful examination of the field of vision, disclosing a *scotoma*, may locate the foreign body. The site of the wound of *entrance* and the probable *direction* which the foreign body took must be taken into account. In most instances, an *x-ray photograph* will reveal its presence and position. If it be of iron or steel, the *giant magnet* (Fig. 197) will frequently indicate its presence by the production of pain when the point is brought near the eyeball, or by the bulging of the iris or the forward movement of the lens when the particle is within these structures. The use of the *sideroscope*, a magnetic needle suspended upon a silk thread, will also aid in the diagnosis.

Treatment.—If the substance is a piece of *iron or steel*, an attempt to extract it with a *magnet* should be made at once. We should also try to remove *other foreign bodies* (glass, wood, copper, lead) as soon as possible after they have been located, by means of delicate forceps; these are introduced through the original wound or through an opening into the vitreous cavity made at the point at which the foreign body has been located. But if this does not seem feasible, they should be left alone, especially if there be no symptoms of infection or irritation, and the patient can be kept under constant observation; in such cases, however, the question of enucleation must be considered (p. 76).

Magnet Extraction.—Instruments used for the extraction of particles of iron or steel are of two kinds: (1) Medium-sized, or *portable electro-magnets* (Hirshberg's, Johnson's, Sweet's, Lippincott's), and (2) large, or *stationary electro-magnets* (Haab's, Volkman's). In using the former (Fig. 198), the point of the magnet is passed through the entrance wound, or through an opening made at the location of the foreign body, and then the current is turned on. If the large magnet of Haab or Volkman be employed, the patient approaches the

magnet, the eye is brought toward the point of the instrument (Fig. 197), and the current gradually turned on; the particle of iron or steel may be drawn out through the original wound,

FIG. 197.—Haab's Giant Electro-Magnet.

FIG. 198. — Medium - Sized, Portable Electro-Magnet.

or an attempt made to draw it from the vitreous, around the lens, into the anterior chamber, from which it is then removed through a corneal incision.

Even after successful extraction, the *prognosis* is always *serious*; about one-third of the patients recover useful vision; in quite a number the form of the eyeball is preserved; in many cases destructive inflammation supervenes. If the attempt at extraction fails, enucleation is usually necessary.

CHAPTER XVII.

DISEASES OF THE LENS.

Anatomy and Physiology.—The *crystalline lens* is a *transparent*, colorless body, *biconvex* in shape, suspended in the anterior portion of the eyeball, between the aqueous and the vitreous chambers. It presents an anterior and a posterior surface, the latter being the more curved, an anterior pole, a posterior pole, and a rounded circumference, the equator. It is devoid of blood-vessels except in fœtal life, its nourishment being derived from the ciliary body. It is enclosed in a transparent *capsule*, and held in position by its *suspensory ligament*. The adult lens consists of a peripheral portion, the *cortex*, and a central part, the *nucleus*. The cortex is semi-solid, softer than the nucleus, and colorless; the nucleus is harder and has a yellowish tint; there is, however, no sharp limitation, the transition being gradual. The nucleus increases in size with advancing years, and the cortex diminishes in proportion; in old age the entire lens is of the consistence of the nucleus and is hard and unyielding; this change is known as *sclerosis*.

In *structure* the lens consists of concentric *laminæ* formed of long, *hexagonal fibres*, the edges of which are connected by a cement substance, leaving fine lymph channels. The fibres either start or end along *Y-shaped or stellate figures*, the lines of which radiate from the anterior and posterior pole to the equator, each fibre encircling the latter; the septa corresponding to the branches of the stellate figure divide the lens into *sectors*. These stellate and Y-shaped figures can often be recognized in the adult lens by oblique illumination.

The *capsule of the lens* is a thin, homogeneous, elastic membrane which covers the lens, being known as the *anterior capsule* in front, and as the *posterior capsule* behind. The anterior capsule is the thicker, and its posterior surface is lined by a layer of cuboidal epithelium from which the lens fibres are formed.

The *suspensory ligament of the lens* is a delicate membrane, extending from the ciliary body to the lens capsule. It covers the inner surface of the ciliary body from the ora serrata to the apices of the ciliary processes, and then passes to the lens, dividing into three layers attached respectively to the anterior capsule, the equator, and the posterior capsule. Between these layers and the equator of the lens is an annular space, triangular on section, known as the canal of Petit; it communicates with the posterior chamber by means of slit-like apertures between the fibres of the anterior portion of the suspensory ligament.

The *function* of the lens is to *focus rays* so that they form a perfect image on the retina. To accomplish this, the refractive power of the lens must change with the distance of the object, according to whether the rays are parallel or divergent. This alteration in the refractive power of the lens is known as *accommodation*, and is produced by a change of shape mainly affecting its anterior curvature.

The lens presents *variations* in physical characteristics at *different periods* of life. *In the fetus*, it is nearly spherical, slightly reddish, and softer than at a later period. *In the adult*, its anterior surface is less convex than the posterior, and its substance is firmer. *Sclerosis*, which consists of a process of toughening, due chiefly to loss of water, begins in the centre of the lens in childhood and advances slowly until adult life, after which its progress is more rapid, increasing the size of the nucleus at the expense of the cortex. *In old age*, the lens increases in size, is flattened, and assumes a *yellow* tinge, becoming tougher and less transparent; this process of sclerosis accounts for the *gray reflex* seen in the pupil of the aged, which may be mistaken for cataract (*senile reflex*); it also explains the inability on the part of the lens of advanced years, to change its shape for the purposes of accommodation (*presbyopia*).

CATARACT.

A cataract is *any opacity of the lens or of its capsule*.

Varieties. — Cataracts may be divided into: 1. *Primary* when independent of any other ocular disorder, and 2. *Secondary or Complicated*, when accompanying or following some other disease of the eye, such as glaucoma, uveitis, etc. The name secondary cataract is also given to the opacity resulting in the *remains of the lens capsule* or lens substance after cataract operations; *after-cataract* is, however, a better term for this form.

Cataracts are divided according to the *part of the lens involved* into:

1. *Lenticular*, situated in the substance of the lens.
2. *Capsular*, affecting the capsule.
3. *Capsulo-lenticular*, involving both lens and capsule.

They are also known as

1. *Partial*, limited to some part of the lens.
2. *Complete*, involving the whole lens.
3. *Stationary*, when they remain incomplete.
4. *Progressive*, spreading, tending to affect whole lens.

Stationary Cataracts may be divided into:

1. *Anterior polar.*
2. *Posterior polar.*
3. *Lamellar.*
4. *Various uncommon forms.*

Progressive Cataracts may be divided into:

1. *Senile* { Cortical.
Nuclear.
2. *Congenital and Juvenile.*
3. *Traumatic.*

In patients *under thirty-five* all cataracts are of *soft* consistence throughout and *white* in color; such cataracts have no hard nucleus and are known as *soft cataracts*. *After this period*, the nucleus becomes *hard* and of a *yellowish* tint, and the lenticular opacity is known as *hard cataract*.

Etiology.—According to etiology, cataract may be classified as:

1. *Congenital*, due to faulty development or intra-uterine inflammation of the eye. To this class belong the anterior and posterior polar, lamellar, and occasionally complete cataract.

2. *Senile*; this is the most common form. It usually appears after the age of fifty. The real cause is unknown. Heredity has some influence.

3. Due to *General Diseases*: diabetes and less frequently nephritis, gout, and general arterial disease.

4. *Traumatic*, by the production of an opening in the capsule, thus allowing the lens to absorb aqueous humor; occasionally by mere concussion.

5. Due to *Ocular Diseases*, causing complicated or secondary cataract; the most common examples are severe forms of ulcerative keratitis, iridocyclitis, choroiditis, myopia of high degree, glaucoma, and detachment of the retina.

Symptoms.—There is (1) *diminished acuteness of vision*, depending upon the situation and the kind of cataract. It is greatest when the opacity is central and diffuse, and least when the cataract is peripheral. When central, the patient sees best in dim light—with dilatation of the pupil. The interference with vision increases with the progress of the

cataract, until finally there is mere perception of light. (2) The patient complains of *seeing spots* which occupy a fixed position in the field. (3) Occasionally there is annoying diplopia or polyopia, due to *irregular refraction* of the lens. (4) Myopia often develops during the early stages, due to increased density and refractive power of the lens; for this reason the patient may be able to discard his reading-glasses for the time; this condition is popularly known as "*second sight*."

Physical Signs.—There are *no inflammatory symptoms*. Examination by *oblique illumination* will show a *grayish* or *whitish opacity* on a black ground, and with the *ophthalmoscope* at a distance, a *black opacity upon a red field* (Plate II). The pupil should be *dilated*, especially in the incipient stage. During the stage of swelling of complete cataracts, the anterior chamber is reduced in depth.

PROGRESSIVE CATARACTS.

SENILE CATARACT.

Senile or Simple Cataract is the *most frequent* form of cataract. It is *quite common after the fiftieth year*; occasionally it is seen as early as forty. Almost always *both eyes* are involved, but generally one in advance of the other. The opacity may begin either in the cortex (*cortical*, Fig. 199), or in the nucleus (*nuclear*, Fig. 200). As a rule, senile cataracts begin in the *cortex* and the nucleus remains transparent throughout the process; a pure nuclear cataract is uncommon. The *time required for full development varies* greatly; it may ripen completely in a few months or may require many years; it may become stationary at any stage of its progress.

The Stages of senile cataract are *four* in number:

1. *Incipient Stage.*—The opacity most frequently begins as *streaks* which extend *from the periphery of the cortex*, where they are wider, to the centre of the lens, where they narrow like the spokes of a wheel (Fig. 199); the periphery is affected first. These streaks appear *grayish by oblique illumination*, and *black* when seen *with the ophthalmoscope*. Between these

sectors the lens is transparent. Less frequently, senile cataract begins with dot-like or cloud-like opacities situated in any portion of the lens; sometimes the portion immediately surrounding the cortex becomes opaque (and exceptionally the nucleus itself), constituting so-called *nuclear cataract* (Fig. 200); the last form causes relatively great visual disturbance. Cataracts sometimes remain *stationary* in the incipient stage, with little impairment of vision. Hence it is often wise not to alarm the patient by acquainting him with his condition, at the same time communicating the knowledge to a relative, for our own protection.

FIG. 199.—Senile Cortical Cataract. A, Seen with Oblique Illumination; B, Section of the Lens; C, Seen with the Ophthalmoscope.

2. *The Stage of Swelling (Maturing Stage).*—The lens absorbs fluid, *swells*, and by pushing the iris forward, *reduces the depth of the anterior chamber*. It appears *bluish-white*, shining, and presents distinctly the markings of the *stellate figure*. During this stage, the *iris casts a shadow upon the lens* when the eye is illuminated from the side, since the superficial portion of the lens is still transparent, and hence the opaque layer is some distance behind the iris.

FIG. 200.—Senile Nuclear Cataract. A, Seen with Oblique Illumination; B, Section of the Lens; C, Seen with the Ophthalmoscope.

3. *Mature Stage.*—The lens loses most of its fluid, *shrinks* somewhat, and becomes *perfectly opaque* and of a *dull gray or amber* color, the *stellate markings* still being recognizable. The *anterior chamber* regains its *normal depth*, and there is *no shadow* thrown by the iris on the lens with focal illumination. Occasionally, the entire lens is changed into a hard, dark-brown mass (*black cataract*). In this stage, the cataract can easily be separated from the capsule of the lens; it is then said to be "*ripe*" for operation, since it can be extracted without leaving much if any of the cortex behind, thus diminishing the chances of subsequent opacity (after-cataract).

4. *Hyper mature Stage.*—The cataract may continue in the mature stage for a long time. If changes continue, the surface of the lens *loses its radial markings* and becomes *homogeneous*, or presents irregular spots. The cataract may continue to lose water, and thus a *shrunk*, dry, flattened mass results (*shrunk cataract*), with some deepening of the anterior chamber. Or, the cortex may become soft, liquid, and milky, and the nucleus sink to the bottom of this fluid (*Morgagnian cataract*), the cataract appearing white with a brownish coloring below. Very old hyper mature cataracts often present the deposit of *cholesterin* or of *lime* salts; the latter change (*chalky cataract*) is found chiefly in complicated cataracts. The anterior capsule may become thickened and opaque (*capsulo-lenticular cataract*). The lens (and iris) may become *tremulous* through stretching of the suspensory ligament. For these reasons, operation upon overripe cataract is less favorable and more difficult than during the mature period.

Pathology.—Senile cataract results from *shrinkage* of the nucleus together with the lens fibres, and presence of *fluid* in the spaces thus created. The *lens fibres* then *swell*, become *cloudy*, and *disintegrate*. The *nucleus* usually remains *unchanged*.

Treatment.—*Extraction* of the lens by operation is the *only* means for relieving a patient of senile cataract. No medicinal treatment, whether local or constitutional, is of curative value.

In the incipient and maturing stages the eyes should be *rested* as much as possible, *correcting lenses* be worn if an error of refraction exists, deranged conditions of the system looked after, and *neighboring ocular disease* be treated. The patient should present himself for examination from time to time. In cases in which the opacity is central, sight may be improved temporarily by the instillation of a weak solution of *atropine* ($\frac{1}{2}$ gr. to $\frac{5}{8}$ i.) to cause mydriasis and enable the patient to see through the peripheral, transparent portion of the lens.

The most favorable time for extraction of senile cataract is when the lens is *completely opaque* and there is no shadow thrown by the iris—*i.e.*, when the cataract is *ripe*. If operated upon before this time, the lens is not always removed

cleanly and some transparent cortex is apt to adhere to the capsule and be left behind; this becomes opaque subsequently, and is absorbed slowly, or an after-cataract develops necessitating another operation—discission; besides, the remains of cortex after extraction tend to produce irritation and interfere with smooth healing.

As a general rule, we operate when the cataract of one eye is *complete*, and the other has progressed far enough to cause considerable *interference with vision*. But there are a number of exceptions to this rule: For instance, when the occupation and circumstances of the patient are such that being unable to work, he cannot wait for the cataract of the first eye to become ripe; or when the cataract shows signs of hypermaturity before the second eye is very much affected. Removal of both cataracts should never be performed at one sitting. When both eyes are affected, useful vision may be abolished before either cataract is ripe.

Artificial Ripening is sometimes resorted to; this is accomplished by preliminary operations consisting of gentle *massage* applied to the lens directly or through the cornea. An incision is made through the periphery of the cornea and the aqueous humor allowed to escape, so that the cornea falls against the lens; then the cornea over the pupil is stroked with a smooth instrument, or the spatula or spoon may be introduced into the aqueous chamber and applied directly to the anterior capsule. Such direct or indirect massage may be done with or without an accompanying iridectomy. Following such operations, the lens becomes opaque after a few weeks, and can then be extracted. Ripening operations are, however, not always reliable nor entirely free from danger; it is now generally considered *safer and better to remove the immature cataract* than to resort to such artificial ripening. Many operators regard the condition of immaturity in a cataract as adding very little to the risks of extraction, especially since the tenacious cortical remnants may be washed out by the injection of a warm, sterile saline solution (0.6 per cent.) into the anterior chamber.

Simple Extraction and Combined Extraction.—Extraction

may be performed *with* (*Combined Extraction*) or *without* (*Simple Extraction*) an *iridectomy*; the question as to which is the better operation has been much discussed. *The simple operation* (without *iridectomy*) is probably now performed in fully one-half of the cases; its disadvantage is the danger of *prolapse of the iris*. *The combined extraction* (with *iridectomy*) is indicated when the iris interferes with the easy delivery of the lens, or protrudes during the operation and cannot be reduced, when the lens is very large, when we suspect that the patient may not behave well after the operation, or when any ocular complications exist. In ordinary cases, *simple extraction is preferred*, since it leaves a *round pupil* without the optical defects of a coloboma, and hence an improvement in vision and appearance. Some operators perform a *preliminary iridectomy*, and an extraction several weeks later, as a means of lessening the dangers of extraction when complications are feared.

Monocular cataract is not generally removed, since, owing to the difference in refraction, the eyes will not work together. Extraction may, however, be performed in such cases for cosmetic effect, to prevent hypermaturity, and to extend the field of vision on the affected side.

Aphakia.—After the extraction of cataract, the patient is compelled to wear *strong convex glasses*, since as a result of loss of the lens (*aphakia*), there is a *high degree of hyperopia and absence of the power of accommodation*. This hyperopia amounts to about 10D. With it there is usually considerable *astigmatism* (2 to 3D), generally “against the rule.” In an average case, therefore, a convex spherical lens of about 10D, combined with a convex cylinder of 2 to 3D, must be worn for *distant vision*; to this sphero-cylinder an additional convex sphere of 3 or 4D must be added for *reading*. Any previous error of refraction will, of course, modify this correcting lens. Glasses should not be prescribed until all signs of irritation have disappeared—generally at the end of a month. Changes in refraction may continue for several months. *The aphakial eye* presents, besides hyperopia and loss of accommodation, a *deep anterior chamber* and usually a *tremulous iris*; the images

normally seen on the anterior and posterior surfaces of the lens are absent.

Prognosis.—A *favorable result and useful vision* follow cataract extraction in the great majority of uncomplicated cases (ninety-five per cent.); there is very often excellent sight, and occasionally perfect vision. The *prognosis* is dependent not only upon *skilful operation*, but upon *careful selection*, and upon exclusion of those complicated cases which cannot be improved by an operation, no matter how successful. Hence it becomes important to diagnose properly the condition of the other ocular structures, and especially that of the *retina*. This is done by *testing the field of vision* with the candle for *light perception* and *light projection*. There should be a good field and good perception and projection of light.

Projection is tested by throwing light from the mirror of the ophthalmoscope upon the upper, lower, inner, and outer portions of the pupil; there is good projection, if, without moving the eyes, the patient is able to state correctly the direction from which the light comes. This test may also be applied with the lighted candle made to approach the eye from various directions, at a distance of one metre and also at a greater distance—three to four metres. Although the cataract be fully matured, there should be good perception of light, even with faint illumination; fingers can frequently be counted at several inches.

CATARACT EXTRACTION.

Indications.—The operation of extraction is indicated for (1) the removal of all *senile cataracts* which are considered fit for operation; (2) soft cataracts after the age of fifteen (sometimes before this period); (3) soft cataracts which have been needled, or traumatic cataracts when glaucoma intervenes or to expedite cure; and (4) sometimes complicated cataracts.

The following description applies to the method of performing *simple extraction* (without iridectomy), as most commonly done.

Instruments Required: (1) An eye speculum (Fig. 201); (2) a fixation forceps (Fig. 202); (3) a narrow Graefe knife

(Fig. 203); (4) a cystotome, straight (Fig. 204); or bent (Fig. 205); if bent, one is required for the right and one for the left eye; (5) a Daviel spoon (Fig. 206); (6) a Knapp metal spatula and probe (Fig. 208); (7) a wire lens scoop (Fig. 207). Since it may be necessary to do an iridectomy, we must have ready, (8) curved iris forceps (Fig. 186); and (9) curved iris scissors (Fig. 188).

Operation.—1. *The Corneal Section.* Local anæsthesia by *cocaine* or *holocain* is ordinarily used, rarely a general anæsthetic. The operator stands behind the patient and inserts the eye speculum; the patient looking down, he seizes the eyeball near the lower margin of the cornea with the fixation forceps held in one hand, and makes the corneal section with the other. This section comprises a *little less than one-half of the circumference of the cornea* and is in the plane of its transparent margin. The *Graefe knife* is thrust into the corneal margin just above the horizontal meridian, traverses the anterior chamber, and emerges at a point opposite the puncture (Fig. 209). Pushing the knife forward and cutting upward by a to-and-fro movement, the section is completed in the same plane, close to the iris, terminating at the upper margin of the cornea, where a small conjunctival flap is usually made. If the operator is not ambidextrous he must stand in front and to the left of the patient when operating on the left eye, so as to hold the knife in the right hand.

2. *Opening the Capsule (Capsulotomy).*—The cystotome is introduced flatwise into the anterior chamber from the temporal side, its point is turned toward the capsule, and this is cut gently and without pressure. There are many different methods of opening the capsule. It may be cut at the periphery by pushing the end of the cystotome beneath the upper part of the iris, turning it and making an incision concentrically with the corneal margin; or the incision may be T-shaped, or A-shaped, or + -shaped.

3. *Delivery of the Cataract.*—The speculum and fixation forceps are removed, and the lens is expelled by pressing gently upon the lower part of the cornea toward the centre of the globe, with the back of a Daviel spoon. This causes gap-

ing of the section, in which the lens presents (Fig. 210). After a greater part of the lens has passed through the corneal wound, the spoon is made to follow up the lowest part of the cataract, which is thus delivered and received upon the wire loop. If the pupil is unyielding, and the iris impedes

FIG. 209.—Corneal Section in Cataract Extraction.

FIG. 210.—Delivery of the Lens in Cataract Extraction.

the exit of the lens, it may be pressed backward with the wire loop or a special iris retractor.

4. *Cleansing ("Toilet") of the Wound.*—A few drops or more of an antiseptic solution are instilled, the lids closed for a few minutes, after which the eye is inspected. If there are any cortical remnants, these should be removed by rubbing the edge of the lower lid upward over the cornea and by stroking with the spatula; blood clots may be expelled in the same manner; the lips of the wound must also be freed from lens particles with the spatula. Care should be taken that the lashes do not touch the wound. Sometimes the anterior chamber is irrigated with a special, delicate syringe or irrigating apparatus (McKeown's, Lippincott's), using warm sterilized saline solution (0.6 per cent.); but as a rule this is found unnecessary, especially if no remnants of cortex seem to have been left. If the iris fails to regain its natural position, we exert gentle pressure upon the lower margin of the cornea, so as to cause the wound to gape and thus disentangle

the iris; if this does not succeed it will be necessary to introduce the spatula into the anterior chamber, and smooth out the iris until the pupil becomes round and central. If we fail in this, and the iris shows a tendency to become displaced again or to prolapse, a small portion is excised. The patient is now allowed to count fingers, and the eye again inspected with oblique illumination. The conjunctival flap is next adjusted, the eye washed out with a few drops or flushed with a greater quantity of antiseptic solution, and the lids are closed.

5. *Dressing.*—The dressing varies with different operators. Most operators cover the lids of both eyes with gauze and absorbent cotton soaked in an antiseptic solution, upon which a greater or lesser quantity of dry absorbent cotton is placed, and then confine these with a binocular bandage. Some surgeons retain the dressings by strips of isinglass plaster. The lids are occasionally closed by a piece of isinglass plaster without any other dressing. Sometimes various protective covers (aluminum, wire, mica, stiff cloth, Fig. 211) are used to prevent injury to the operated eye.

FIG. 211.—Ring's Ocular Mask.

After-treatment.—The patient is directed to lie quietly upon his back; an anodyne is often advisable. After twenty-four hours he may change to the side of the unoperated eye. His food should be fluid. The bowels need not be emptied artificially for three or four days; if the patient has a movement before this, he must be cautioned not to strain. The wound is inspected after twenty-four hours; if any prolapse of iris has occurred, it is excised. If the pupil is central and round, atropine is instilled after the third day. On the fourth or fifth day the unoperated eye may be left free, and the patient may sit up in bed for an hour or two; after a week a light dressing (Fig. 358) is applied and the patient may sit in an

easy-chair the greater part of the day; after two weeks nothing but smoked glasses need be worn.

Modifications in the Operation.—A great many operators make a small iridectomy in *every* cataract extraction (*Combined Extraction*); the indications for this are given on p. 198. There are a great many modifications in the situation of the section.

Linear Extraction.—In this modification, a *small corneal section* is made for the removal of *soft* and *traumatic* cataracts, and cataract masses produced by needling; the operation is performed as follows: With the lance-shaped knife an incision about 5 mm. wide is made near the margin of the cornea, and then the capsule is torn with the cystotome. The soft lens masses are evacuated by depressing the posterior lip of the wound with the wire loop. A small iridectomy is sometimes combined with this operation.

The Complications of Cataract Extraction include loss of vitreous, dislocation of the lens, insufficient opening in the cornea or capsule, wounding the iris, prolapse of the iris, incomplete evacuation of the cataract, and intraocular hemorrhage.

The Complications in the Healing-Process include prolapse of the iris, striated keratitis, glaucoma, iritis, iridocyclitis, cyclitis, suppuration of the wound, panophthalmitis, and intraocular hemorrhage.

Congenital Complete and Juvenile Complete Cataracts are *infrequent*. The lens is uniformly *white* or *bluish-white*, or it may have a pearly lustre. It is *always soft*. Sometimes it is fluid and milky. These forms of cataract may occur in eyes which are otherwise perfectly healthy, or they may be complicated cataracts, with changes in the retina, choroid, or optic nerve. One or both eyes are affected. The *congenital* complete cataract is due to a disturbance of development or to some intrauterine ocular inflammation. The complete cataract of young people (*juvenile*) may be due to heredity, or arise without known cause; in some cases, there is a history of previous convulsions.

Treatment consists in *discission (needling)*; this should be done as *early as possible*, so that disuse of the function of

sight may not cause amblyopia. The needle operation must usually be repeated a number of times; sometimes there are remains of the lens which do not become absorbed and must subsequently be removed by extraction. Semifluid cataracts are removed by linear extraction.

Traumatic Cataract is the result of a *perforating wound of the lens capsule*; occasionally it ensues after contusions of the eyeball, without perforation (concussion cataract), though probably a rupture of the capsule occurs in such cases. Within a few hours after the injury the lens becomes *cloudy* at the seat of the wound from absorption of aqueous humor, and *swells*; opaque and swollen *lens substance protrudes* through the wound in the capsule and often falls into the anterior chamber; the swelling and clouding continue until, after a few days, the *entire lens has become opaque*. Then the lens substance becomes *absorbed*; in favorable cases in young persons, this process continues until there is *spontaneous cure* with a clear, black pupil. More frequently, however, part of the lens *remains opaque* in the capsule and requires subsequent operation. Occasionally the opacity of the lens remains limited to the injured portion, due, probably, to closure of a small capsule opening; in rare cases such a stationary cataract becomes absorbed. The course described may be less favorable: *Inflammation of other parts* of the eye may result—iritis or iridocyclitis, or when infection occurs, panophthalmitis. The swelling of the lens may cause *iritis* or *glaucoma*.

Treatment.—Immediately after the injury, absolute *rest, iced compresses*, and *atropine* are to be employed. If the rapid swelling of the lens causes inflammation or much *increase of tension*, the cataract should be removed by *extraction*. But if such complications do not arise, it is wiser to *allow absorption to proceed*, and to defer operative intervention until there is no irritation or inflammation, and spontaneous improvement has come to a standstill.

DISCUSSION OF THE LENS (NEEDLING).

Indications.—(1) In zonular, congenital complete, and juvenile complete cataracts (*soft cataracts*), previous to the fif-

teenth year; (2) preliminary to extraction in cases of high degree of *myopia*; (3) occasionally as a means of ripening senile cataract. Discission is also used for dividing *after-cataract*.

FIG. 212.—
Knapp's Knife-
Needle.

Operation.—In very young children a *general anæsthetic* is required; in others, *local anæsthesia* is sufficient. The *pupil* must be *dilated*. The speculum is introduced and the eyeball steadied with the fixation forceps. A knife-needle (Fig. 212) is thrust through the outer portion of the cornea and then through the capsule of the lens, making two cross cuts, each about 4 mm. in length (Fig. 213). These cuts must be superficial, especially if this is the first operation, so that there will not be too rapid swelling of the lens. The lens substance may be broken up a little by rotating the needle. After some of the swollen lens matter has been absorbed (several weeks), the operation must be repeated; at the second operation the discission may be deeper and bolder.

At the last of the several operations, the incision must include the posterior capsule.

After-Treatment.—There is usually very little reaction. The pupil must be kept dilated with atropine. The lens substance swells, protrudes through the opening in the capsule, and pieces fall into the anterior chamber and become absorbed. Usually three operations are required. The entire duration of treatment is several months.

Complications.—*Rapid and extensive swelling* of the lens may cause secondary *glaucoma* requiring *removal of the lens* by linear extraction, with or without iridectomy. A bold discission is sometimes done, with a view of extracting the lens a

FIG. 213.—Discission of the Lens.

few days afterward, as soon as there is marked swelling; this is the usual procedure when the lens is removed in high degrees of myopia. *Iritis* may occur after discission, occasionally iridocyclitis, and very rarely loss of the eye.

The Suction Method is occasionally used after discission of soft cataracts, and in fluid or semifluid cataracts: A small corneal wound is made and the capsule lacerated; by means of a tube the lens matter is sucked out, either by mouth or suction-syringe. This method is not in general use.

STATIONARY CATARACTS.

Anterior Polar Cataract (*Pyramidal Cataract*).—This lenticular opacity occurs in the form of a *small*, round, white opacity, often pyramidal in shape, situated at the *anterior pole* of the lens, beneath the capsule (Fig. 214). It may be *congenital* or *acquired*. The acquired form originates from an

FIG. 214.—Anterior Polar Cataract. *A*, Seen with Oblique Illumination; *B*, Section of Lens; *C*, Seen with the Ophthalmoscope.

FIG. 215.—Acquired Form of Posterior Polar Cataract. *A*, Seen with Oblique Illumination; *B*, Section of the Lens; *C*, Seen with the Ophthalmoscope.

ulcer of the cornea in early childhood. Such an ulcer perforates and allows contact and pressure between lens and cornea, setting up an irritation in the anterior capsule which results in a proliferation of the subcapsular epithelium; afterward the anterior chamber is restored; sometimes there is an accompanying corneal opacity. As a rule this form of cataract does not interfere with vision sufficiently to require treatment.

Posterior Polar Cataract.—This form may be *congenital* (*capsular*) or *acquired* (*cortical*).

The *congenital* form is a *capsular* opacity consisting of a *small*, *round*, *white* deposit, situated at the posterior pole; with the ophthalmoscope it appears as a black dot upon the red fundus-reflex. It represents the *remains of the hyaloid*

artery at the point of attachment to the posterior capsule of the lens. It causes but trifling interference with vision and requires no treatment.

The *acquired* form is a *grayish, stellate* opacity of larger size, situated in the *cortical* layer of the lens, at its posterior pole (Fig. 215). It is a form of *secondary* cataract which develops in connection with high myopia, choroiditis, disease of the vitreous, and retinitis pigmentosa. It remains *stationary* for many years, but is apt finally to become *complete*. In this affection there is considerable *impairment of vision*, caused not only by the cataract, but also by the accompanying disease of the deep structures. It does not admit of treatment.

Lamellar or Zonular Cataract.—This variety of *partial, stationary* cataract is either *congenital* or forms in early *childhood*, and usually affects *both eyes*. It is the most common form of cataract seen in children. It is sometimes hereditary, and often associated with a history of convulsions

FIG. 216.—Zonular Cataract. A, Seen with Oblique Illumination; B, Section of the Lens; C, Seen with the Ophthalmoscope.

and with the changes of rickets, especially in the teeth and bones. It consists of a *gray, disc-like* opacity of the layer surrounding the *transparent nucleus*, with clear cortex on the outside (Fig. 216). When the pupil is dilated, examination by oblique illumination shows a *grayish disc surrounded*

by clear lens substance; from the margin of the opacity short striæ are often seen projecting into the surrounding transparent cortex. The cataract is *most dense at the margin of the disc*; this distinguishes it from nuclear cataract. By the use of the ophthalmoscope at a distance, the cataract presents a dark disc surrounded by a zone of red fundus-reflex; the disc is somewhat lighter in the centre than at the periphery, and in the former situation allows some light to pass.

Lamellar cataract usually remains *stationary*, but occasionally becomes *complete*. It causes *interference with vision*; the amount may be slight or decided, depending upon the extent and density of the opacity.

Treatment.—When sight is considerably interfered with we can improve vision by *iridectomy*, by *discission* in the young, or by *extraction* in older persons. *Iridectomy* (small coloboma downward and inward) is indicated when the vision is very materially improved after the use of a mydriatic; its advantages are that the patient does not require strong convex lenses and often retains binocular vision; its disadvantages are the elongated pupil, and some dazzling due to this. Removal of the lens by *discission* or *extraction* is indicated in those cases in which there is little or no improvement in sight after dilatation of the pupil, and when there are indications of progress of the cataract.

Various Uncommon Varieties of Stationary, Partial Cataract are met with. These include (1) *central* cataract, a small, white opacity in the centre of the lens, (2) *fusiform* cataract, a spindle-shaped opacity running from the anterior to the posterior pole, and (3) *punctate* cataract, consisting of a number of very small, white dots variously distributed through the lens. These opacities are usually *congenital*, cause *little interference with vision*, but are often associated with other ocular defects.

Complicated or Secondary Cataracts *accompany or follow other diseases of the eye.* The most frequent ocular affections which lead to cataract are iridocyclitis, choroiditis, severe forms of corneal ulcers, glaucoma, retinitis pigmentosa, and detachment of the retina. Such cataracts frequently begin in the *posterior* part of the lens, often have distinctive features, and tend to *degenerate*. It is important to establish the fact that a cataract is complicated when the question of operation presents itself. The *treatment* of complicated cataract is usually very *unsatisfactory* and the *prognosis* is always *less favorable* than in uncomplicated cases. This is because the operation is rendered difficult and the effect on sight disappointing by the complicating ocular disease; many cases cannot be operated upon.

After-Cataract (often called *Secondary Cataract*) is an opacity found in the situation and plane of the pupil, *after a*

cataract operation ; it consists of remnants of *lens cortex*, of proliferation of remaining subcapsular *epithelium*, or of *products of inflammation* (new connective tissue). The *membrane* thus formed may be thin and delicate or thick and tough, and the degree of subsequent diminution in the improvement in sight following the cataract operation will vary accordingly. When due to inflammatory products, the membrane is apt to be thick and the iris adherent.

Treatment consists in *dividing* the membrane (*discission*), after all signs of irritation or inflammation have subsided (two or three months).

Discission for After-Cataract.—If the opacity is thin and delicate it is divided by means of Knapp's *knife-needle* (Fig. 212) introduced through the periphery of the cornea, the pupil having previously been dilated ; a T-shaped or + -shaped incision is made, care being taken that the instrument is sharp, and that there is no dragging on the iris or ciliary body, for fear of subsequent inflammation. Such membranes are sometimes cut by introducing the knife-needle from behind, through the sclera. If the membrane is thick and tough, it may be divided by *two knife-needles*, one entering at each side of the periphery of the cornea, meeting in the centre of the pupil and then separating. The membrane and iris may be cut with the Graefe knife (*iridotomy*, p. 146), or it may be extracted by *irido-cystectomy* (p. 146). Discission of after-cataract is sometimes followed by *glaucoma*, and occasionally by *iridocyclitis* and suppuration.

DISLOCATION OF THE LENS.

Dislocation of the lens may be *partial* (*subluxation*) or *complete* (*luxation*).

Symptoms are *disturbance of vision*, interference with *accommodation*, a change in *refraction*, *monocular diplopia*, and *tremulous iris*. They differ according to whether the displacement is partial or complete. In addition there are complications and sequelæ which are often *serious*.

Partial Dislocation (Subluxation) may consist of a *tilting* of one edge of the lens, or of a *lateral displacement*—upward,

downward, inward, or outward. In such cases the *anterior chamber* will be of unequal depth, being *increased* where the lens is absent. The *convex edge of the lens* can usually be seen (Fig. 217) in some part of the pupil, the portion of the latter which is free from lens being particularly black. With the indirect method of ophthalmoscopy, the optic *disc appears double*, one image being seen through the lens and the other through the free pupil. Movements of the eyeball disclose a tremulous condition of the lens and iris (*iridodonesis*). There is considerable *myopia* in the area corresponding to the lens, the convexity of the latter being increased through relaxation of the suspensory ligament; also marked *astigmatism*. *Monocular diplopia* is complained of, two images being formed on the retina. The subluxated lens may become *opaque*, and this adds to the visual disturbance.

FIG. 217.—Dislocation of the Lens Upward and Outward.

Complete Dislocation (Luxation) occurs when the lens is displaced *anteriorly* into the aqueous, or *posteriorly* into the vitreous cavity. In traumatic cases in which there is rupture of the sclera, the lens may lie *beneath the conjunctiva*.

When dislocated *anteriorly*, the lens is easily recognized. If transparent, it looks like a large drop of oil with a curved, golden margin when seen by oblique illumination. The anterior chamber is increased in depth.

When displaced into the *vitreous*, the lens sinks into the lowest part, and either becomes attached to the fundus by exudation or moves about; when opaque, it can be seen with the ophthalmoscope and sometimes with the unaided eye. The anterior chamber is deep, the iris tremulous, and the pupil very black. The eye is, as in aphakia, in a condition of extreme hyperopia and has lost its power of accommodation.

Complications and Sequelæ.—A *partial* dislocation often changes to a *complete* one. When subluxated, the lens may remain clear a long time, but completely dislocated lenses soon become *opaque*. Choroiditis and iridocyclitis, secondary glaucoma, and even sympathetic ophthalmia sometimes follow. Displacement into the vitreous is tolerated better than anterior luxation.

Etiology.—Dislocation of the lens may be either *congenital* or *acquired*. In order that the lens can become dislocated there must be some *defect in the suspensory ligament* such as rupture, stretching, or imperfect development.

The *congenital form* is partial, usually upward, often becomes complete in after-years, is generally bilateral, and often hereditary.

The *acquired forms* are either *traumatic* or *spontaneous*. Traumatic dislocation is generally the result of contusions. The predisposing cause of spontaneous dislocations is a change in the suspensory ligament seen in fluid vitreous, choroiditis, and myopia of high degree, detachment of the retina, and hypermature cataract; the exciting cause may be insignificant, such as various straining efforts.

Treatment.—In *partial dislocation*, if no symptoms of irritation are produced, treatment consists in prescribing suitable glasses, usually *strong convex lenses* to correct the refraction of the aphakial portion. When the lens is *dislocated into the anterior chamber* it should be *removed*, by discission in young persons, by extraction in older cases; the lens should first be pierced by a needle to prevent its dislocation into the vitreous, and be removed by a spoon or wire scoop after corneal incision. If *dislocated into the vitreous*, extraction is indicated but difficult; *strong convex glasses* are prescribed for the aphakia. If inflammatory symptoms arise in a case in which the dislocated lens cannot be removed, an *iridectomy* may be tried; if, in such cases, the eye is sightless, *enucleation* is indicated.

CHAPTER XVIII.

DISEASES OF THE RETINA.

Anatomy.—The retina is a thin, delicate *membrane* which consists, among other parts, of an *expansion of the optic nerve*. It is placed between the hyaloid membrane of the vitreous internally, and the choroid externally. It extends forward to the ciliary body where its termination is called the *ora serrata*; devoid of nerve fibres, simpler and thinner, it is continued over the inner surface of the ciliary body and the posterior surface of the iris. In the living eye, it is *transparent* and of a *purple red color*; under the influence of light, it is quickly *bleached*; after death, it soon becomes opaque and white. The retina is connected with the subjacent choroid at the entrance of the optic nerve and at the *ora serrata*; elsewhere it simply lies upon this tunic but is not attached to it. When we detach the retina, the pigment cells which form its outermost layer adhere to the choroid, and on this account were formerly described as part of the latter.

The *inner surface* of the retina presents in the axis of the eyeball the yellow spot or *macula lutea*, about 1 to 2 mm. in diameter, and in its centre a small depression, the *fovea centralis*; this is the region of most distinct vision, and the part of the retina which is made to receive the image when we wish to get an exact impression of an object. About 3 mm. to the inner side of the posterior pole of the eye is a pale, round area, the *head of the optic nerve* (*papilla* or *disc*), corresponding to the point where the optic nerve pierces the retina (Fig. 40). The circumference of the disc is slightly elevated above the surface of the retina, but the centre presents a depression, the *physiological cup* or *excavation*; here the blood-vessels of the retina enter the eye. The ophthalmoscopic appearances of the background of the eye and the distribution of the retinal vessels are given in Chapter III.

The *central artery* of the retina, accompanied by the corresponding vein, pierces the optic nerve about 2 cm. from the globe, and passes between the bundles of fibres to the inner surface of the retina at or near the middle of the disc. Excepting at the papilla, where minute communications are sometimes found between retinal and ciliary vessels, the retinal arteries have no anastomoses; they are *terminal branches*; hence in obstruction of the central artery there is no compensatory collateral circulation, and blindness results. The retinal vessels lie in the *inner layers*; the external layers are destitute of blood-vessels and are nourished by the adjacent choriocapillaris. The

fovea has no blood-vessels; in this situation, the choriocapillaris is thickened. The blood-vessels are surrounded by lymphatic sheaths forming the *lymphatics* of the retina.

The *minute anatomy* of the retina is very complicated. We distinguish *two kinds of tissue*: (1) *nervous elements*, of which there are eight layers, and (2) *supporting tissue* (Mueller's fibres).

The supporting tissue comprises the internal and external limiting membranes and numerous fibres serving to keep the delicate nerve tissue in proper position.

Microscopic examination shows the following layers of the retina, from within outward (Fig. 218): 1. The *internal limiting membrane*. 2. The *layer of nerve fibres*, consisting of the expansion of the fibres of the optic nerve destitute of medullary layer after piercing the eyeball. 3. The *layer of ganglion cells*, a stratum of large, branching nerve cells. 4. The *inner plexiform layer*. 5. The *inner nuclear layer*. 6. The *outer plexiform layer*. 7. The *outer nuclear layer*. 8. The *external limiting membrane*. 9. The *layer of rods and cones*, the light-perceiving layer. 10. The *layer of pigment cells*, which bounds the retina externally and consists of a single stratum of hexagonal pigmented cells.

The *rods* are much more numerous than the *cones*, excepting at the macula where the cones preponderate. At the *fovea* there are no rods, and the cones, longer and narrower than elsewhere, are found exclusively. In this spot also, all the layers of the retina are much *thinner*, there is no nerve-fibre layer, and Mueller's fibres are arranged obliquely. The *disc* consists of *optic-nerve fibres exclusively*; it has no other retinal nerve elements and has no power of sight; hence it is called the *blind spot*.

Physiology.—*The action of light changes the visual purple* contained in the outer segments of the rods into a colorless substance. When the eye is in the dark, most of the pigment is stored

FIG. 218. — Vertical Section of the Retina (Modified from Schultze). The Numbers refer to the Text.

in the body of the cell and is withdrawn from between the rods. After exposure to light, the pigment granules push their way inward into the processes extending between the rods and cones, and the latter become contracted and shortened. The function of the pigment cells is the renewal of the visual purple of the outer segments of the rods after the bleaching produced by exposure to light.

The *rods and cones*, the *terminal organs of the optic nerve*, receive waves of light which fall upon the retina and convert these vibrations into impulses which are carried by the optic nerves and tracts to the *brain*; here they produce the *sensation of light*. When the image of an object falls upon the *macula*, there is distinct vision; when it falls upon any other part of the retina, there is indistinct vision. Two points give rise to *separate visual impressions* when their images are at least 0.002 mm. apart, since this represents the diameter of the cones at the fovea; images which are closer than this would only stimulate one cone and consequently create but one visual impression. In other words, to be seen distinctly, two objects must subtend a visual angle of one minute or more.

Images of an object give rise to a *single visual impression* when they fall upon *corresponding retinal areas*; otherwise there are double images. In *binocular vision* certain portions of the retina are associated; thus the upper halves of the retinae correspond, as do also the lower halves; but the nasal side of one retina corresponds to the temporal half of the other, and *vice versa*.

Rays of light impinging upon the retina come from the *opposite side of the field*; thus the upper part of the retina is used for seeing objects in the lower part of the field, the temporal portion of the retina for the nasal part of the field, etc. The *image* on the retina is always *inverted*.

Affections of the Retina may be divided into:

a. *Inflammation*, the various forms of *retinitis*: (1) simple, (2) albuminuric, (3) diabetic, (4) leukæmic, (5) syphilitic, (6) hemorrhagic, (7) purulent, (8) uncommon forms of retinal changes.

b. *Vascular Changes*: (1) anæmia, (2) hyperæmia, (3) hemorrhages, (4) arteriosclerosis, (5) embolism, (6) thrombosis.

c. *Pigmentary Degeneration* (retinitis pigmentosa).

d. *Detachment*.

e. *Tumor*: glioma (see chapter on Intraocular Tumors).

RETINITIS.

Inflammation of the retina presents various clinical types. There are, however, certain signs and symptoms which are more or less common to all varieties. Retinitis may be *primary*, or *secondary*, when it is an extension of inflammation of neighboring ocular structures. It usually *extends* to both the *papilla* and the *choroid*. When the involvement of the entrance of the optic nerve is marked, we speak of the affection

as *neuroretinitis* ; when the choroid is prominently implicated, we call the condition *choroidoretinitis*. The disease may be confined to one eye ; but since it is generally dependent upon a constitutional factor, it is almost always *bilateral*. It may be acute in course, but as a rule it lasts many *weeks* or even several months.

Subjective Symptoms.—(1) *Diminution in acuteness of vision* varying with the severity and extent of the retinitis, but generally considerable ; it may be especially marked at night, constituting night-blindness. (2) *Changes in the field of vision* ; there may be concentric or irregular contraction, or scotomata. (3) *Alterations in the shape of objects* : micropsia, objects appearing smaller than they really are ; macropsia, objects appearing larger than normal ; metamorphopsia, a distortion of the shape of objects, straight lines appearing wavy and bulging. (4) *Diminution of the light sense*. (5) Feeling of *discomfort* in the eyes. (6) Photophobia may be present, but pain is rare.

Objective Symptoms.—There are no external signs ; the objective symptoms are all *ophthalmoscopic* : Diffuse *clouding* of retinal details, especially in the region of the papilla ; *congestion of the disc* with *indistinctness of its edges* ; circumscribed *exudations* appearing as soft, white, or slightly yellow spots or patches, discrete or confluent, varying in size, and found principally along the retinal vessels and at the macula ; *tortuosity and distention of the vessels*, which may be obscured in parts by swelling and exudation ; *hemorrhages* of various shapes and sizes, rounded when occurring in the deeper layers, and feathery or flame-shaped when superficial.

Course.—The inflammation *may subside* completely and useful vision return ; or certain *changes may occur* in the retina as a result of atrophy, causing considerable impairment or absolute loss of vision. These changes are : *Atrophy of the retina* allowing the choroidal vessels to become visible ; bright, *white patches and bright dots* replacing hemorrhages or exudation and frequently *pigmented* ; *contraction of the vessels*, which are bordered by white lines ; *atrophy of the disc*, which presents an indistinct outline and a pale, dirty color (*post-*

neuritic atrophy). The *prognosis* depends upon the severity of the inflammation, the parts of the retina most involved, and the clinical form of the retinitis.

Pathology.—The changes consist in *congestion*, *œdema*, *exudation* of white blood corpuscles and of fibrin, *fatty degeneration*, and *extravasation of blood*. The white spots are due to exudation of white blood corpuscles and of fibrin, swelling of nerve fibres and cells, and fatty degeneration of the retinal elements and of exudation.

Etiology.—Retinitis occurs occasionally as a local lesion. But generally it is merely a manifestation of a *constitutional disease*, such as *nephritis*, *diabetes*, *syphilis*, affections of the *vascular system*, etc.

Treatment.—The *local treatment* consists in absolute *rest* for the eyes, *protection from light*, either by smoked glasses or the darkened room, and often the use of *atropine*. *Internally*, we give small doses of *mercury*, also *iodide of potassium*, *diaphoretics*, and sometimes cathartics. In addition, it is of the greatest importance to treat the *constitutional* condition which is the cause of the retinal lesion.

Simple Retinitis (*Serous Retinitis*, *Œdema of the Retina*) is an inflammation of the *superficial* layers of retina, *slight* in degree, and simple or *serous* in type; the evidences of inflammation are limited to *swelling*, *vascular distention*, and occasionally *hemorrhages*. Some authorities regard it, not as a distinct disease, but as the first stage of the more common forms of retinitis; in the latter, the inflammation is of the *parenchymatous* type and the pathological changes are more extensive, involving the deeper layers of the retina, and are capable of causing greater destruction.

Symptoms.—*Impairment of vision*, *distorted vision*, *contraction* of the visual field, and *scotomata*. The *ophthalmoscopic signs* are *hazy picture* of the fundus, especially around the disc, the margins of which are indistinct; *tortuous* and dilated *veins*; the vessels are *hidden* in places by the swelling; and occasionally there are *hemorrhages*.

Etiology.—Many causes have been assigned to this form of retinitis, among them *overuse* of the eyes especially with un-

corrected errors of refraction and with poor illumination, exposure to cold, exposure to *excessive light* and heat, and *sypilis*. It may be the *first stage* of other forms of retinitis. No assignable cause may be found.

Prognosis is often *good* when the affection remains serous in type.

Treatment consists in the *removal of the cause* and the observance of directions given under retinitis in general.

ALBUMINURIC RETINITIS.

Retinitis of Bright's Disease usually presents *well-marked ophthalmoscopic signs* which are *almost pathognomonic*. There are, however, occasional cases of intracranial disease, especially tumor, which give rise to a neuroretinitis resembling that of Bright's disease. It is usually *bilateral*, rarely *unilateral*.

Symptoms.—The subjective symptoms are those of retinitis in general (p. 216). The degree of *disturbance of vision* depends upon the severity of the inflammation and especially upon the position of the exudations and hemorrhages. Minute changes in the macular region will cause considerable reduction in acuteness of vision, while extensive involvement of the rest of the fundus may affect the sight but very little.

Ophthalmoscopic Signs (Plate XVI) are those of retinitis in general: *swelling and haziness* of the retina and of the *papilla*, distention and *tortuosity* of the retinal vessels, especially veins, and *hemorrhages* either in the form of flame-shaped or round spots, or larger extravasations. To these are added the distinctive feature: pure *white spots* found chiefly at the *macula and surrounding the disc*, less frequently elsewhere. *At the macula*, these spots are usually arranged in radiating lines which form a *star-shaped figure* with the fovea for a centre; or when less complete, the lines resemble the sticks of an open fan. Near the disc, and often more or less surrounding it, are *larger white spots*. The white spots found in both of these situations have a certain *brilliancy* due to fatty degeneration of the retinal elements and of the exudation.

Though this is the most frequent form of albuminuric reti-

PLATE XVI.

FIG. 219.—Albuminuric Retinitis.

FIG. 220.—Albuminuric Retinitis (Advanced Stage).

nititis, there are *other and less characteristic pictures* seen in nephritis; there may be simply retinal hemorrhages, simple retinitis, or hemorrhagic retinitis.

Albuminuric retinitis is sometimes described as occurring under *two forms*: 1, the *inflammatory*, when swelling, congestion, and hemorrhages are the predominating features; and 2, the *degenerative*, when the white spots and hemorrhages occur without swelling or congestion. The two forms are usually associated in varying proportions.

Etiology.—The affection is usually a complication of *chronic interstitial nephritis*; much less frequently of chronic parenchymatous nephritis; it may occur with *any form* of nephritis (scarlatina, pregnancy).

Pathology.—There are *sclerotic and hyaline* changes in the *walls of the retinal vessels*, followed by *œdema, inflammation, and degeneration* of the retina.

Course and Prognosis.—Though the retinitis is *usually a late symptom* of Bright's disease, the disturbance of vision may be and not infrequently is the *first symptom* which calls attention to the nephritis. There is *no fixed relationship* between the course of the nephritis, the amount of albumin, and the degree of retinitis. There are cases in which the vision is but slightly affected even in the late stages, and others in which sight is seriously affected quite early. The condition is of *great prognostic importance* and indicates, with but few exceptions, a *fatal termination in from six months to two years*. The *exceptions* usually are cases occurring during pregnancy and scarlatina.

Treatment should be directed to the *nephritis*; no local treatment is of any value.

Gravidic Retinitis is the name given to retinitis *complicating the albuminuria of pregnancy*. Its signs and symptoms are the same as in the other forms of albuminuric retinitis, but they tend to *clear up after delivery*. It usually occurs during the *final months* of pregnancy, and the *prognosis* in regard to vision is often *good*, especially if labor be induced prematurely. When it occurs in the early months, the prognosis is less favorable, and the condition may warrant the in-

duction of abortion in order to prevent further changes in the eyes.

Uræmic Amblyopia is the term used for *loss of sight* during an attack of *uræmia*, *without any changes in the retina*. It occurs in *pregnancy* and during the late stages of *scarlatina*. Similar attacks may also occur in patients who have *albuminuric retinitis*. It appears *suddenly*, affects *both eyes*, and is associated with *other symptoms of uræmia*: headache, vomiting, convulsions, and coma; the pupils are dilated but respond to light. After lasting a short time, or for a day or two, *normal vision usually returns*. *Treatment* is that of *uræmia*.

Diabetic Retinitis occurs as a late manifestation of glycosuria, but is *not common*. The *ophthalmoscopic appearances* resemble those of *albuminuric retinitis* in some cases, but in others they are characteristic: *small, bright, white spots* in and around the *macular region*, grouped *irregularly* and not in the form of a stellate figure; sometimes larger spots; numerous punctate or larger *hemorrhages*; there is *no swelling* of the optic nerve and retina. The *prognosis* depends upon the systemic condition. The *treatment* is that of diabetes.

Leukæmic Retinitis presents marked *swelling* of the retina and disc and numerous *hemorrhages*. The *blood-vessels* are greatly *dilated* and extremely tortuous and the *blood* is very *pale*. The entire *fundus* is *pale* and has a *yellowish* hue. There are white and yellow spots of *exudation*, and some of these present a pink border; they consist of white blood corpuscles surrounded by red blood cells.

Syphilitic Retinitis (*Syphilitic Choroidoretinitis*) is a common form, found in both *hereditary* and *acquired syphilis* (Fig. 167, Plate XIV). In acquired syphilis, it occurs in the *secondary stage*, during the first or second year, and usually involves *both eyes*. It is generally associated with *choroiditis* and often with *iritis*.

Ophthalmoscopic Signs.—*Indistinctness* of the fundus due to *swelling* of the retina and disc, and to fine, *dust-like opacities* of the posterior portion of the *vitreous*; these opacities cause the disc to appear *red and hazy*; scattered grayish or white *spots* often fringed with *pigment*, especially in the macular

region, but also peripherally; circumscribed white *exudations* along the large blood-vessels, forming *white lines*.

Subjective Symptoms consist of more or less *diminution* in the acuteness of *vision*, diminution in the light sense, *night blindness*, annoying *flashes* of light, *distortion* and changes in size of objects, central and ring *scotomata*, and later, *contraction of the field* of vision.

Course and Prognosis.—The progress is *slow* and *relapses* are common. The *prognosis* depends upon the stage during which treatment is begun; if begun early and carried out vigorously, the prognosis is good, though some impairment of vision usually remains. Neglected cases are often followed by disseminated choroiditis, pigmentary degeneration of the retina, and optic-nerve atrophy.

Treatment consists in the thorough use of *mercury* by inunctions and afterward *iodide of potassium*, rest of the eyes, protection from light, and *atropine*.

Hemorrhagic Retinitis presents *numerous and recurrent hemorrhages* added to the other signs of *retinitis*; the extravasations of blood are abundant, and both flame-shaped (superficial) and roundly irregular (deep). This affection usually occurs in *elderly* individuals as a result of diseases of the *heart* and *blood-vessels*, and severe disorders of the *portal circulation*. It may be monocular or bilateral. The *prognosis* is *unfavorable*. New hemorrhages are apt to be added to the residua of the old ones; sometimes the affection terminates in *hemorrhagic glaucoma*. It is often a forerunner of *cerebral hemorrhage*. Treatment consists in rest for the eyes, *smoked glasses*, sometimes local abstraction of blood, and *ergot*. *Constitutional treatment* is of the greatest importance and enables the patient to profit from the warning of the danger of hemorrhages elsewhere which the ocular affection gives.

Purulent Retinitis (*Metastatic Retinitis*) results from the lodgment of *septic emboli* in the retinal arteries in the course of puerperal and other forms of *septicæmia* and *pyæmia*, and also from *infected wounds* and foreign bodies. In the first stage there are small white *spots* and *hemorrhages* around the disc and in the macular region; very soon, however, the

uveal tract is invaded and the signs of *purulent choroiditis* (p. 157) appear. The inflammation ends in *panophthalmitis* or in degeneration of the eyeball without perforation (*pseudoglioma*). Non-infected embolus gives rise to characteristic retinal changes (p. 224).

Uncommon Forms of Retinal Changes.—A number of pathological conditions are found in the retina which, though uncommon, have received names describing the clinical picture in each case. Among these are *Retinitis Circinata* (presenting a crescentic or annular figure formed of white patches surrounding the macula); *Angeoid Streaks* (pigmented striæ resembling a system of obliterated blood-vessels); *Striated Retinitis* (yellowish or grayish streaks radiating from the disc to the periphery); *Punctate Retinitis* (numerous, small, white, or yellowish scattered spots); *Proliferating Retinitis* (dense vascularized masses of connective tissue which project from the retina into the vitreous, p. 187).

Retinal Changes due to Excessive Light are seen after injurious exposure of the eye, (1) to the *sun*, especially in watching an eclipse with insufficient protection, (2) to the *electric light* (electric ophthalmia), as in electric welding, and (3) to sunlight reflected from the *snow* (snow blindness). There are *pigment changes at the macula* and, corresponding to this, a central, positive *scotoma* which may become less marked, but does not disappear entirely. The *conjunctivitis* which results from exposure to excessive light is described on p. 83.

Symmetrical Changes at the Macula in Infancy (*Amaurotic Family Idiocy*).—This condition presents a clinical picture which somewhat *resembles* that of *embolism* of the central artery: a red spot at the macula surrounded by a grayish-white zone about twice the size of the disc; this is followed by *optic-nerve atrophy*. The disease occurs in *infants* who present general muscular and mental *weakness*. There is *gradual loss of sight*. *Death* results in a year or two. It attacks several children of the same parents; all recorded cases have been of Jewish parentage.

Contusion of the Retina (Edema of the Retina) is a *transitory clouding* of the retina resulting from *contusion* of the

eyeball. It causes some diminution in acuteness of vision, which *disappears* with the retinal change in a few days.

CIRCULATORY DISTURBANCES OF THE RETINA.

Hyperæmia of the Retina, when slight, is recognized by *increased redness of the disc* and by *slight striation* of its margins. Such a condition is often found in persons suffering from the effects of errors of refraction (*asthenopia*) and in those whose vocations expose the eye to *excessive light or heat*. Marked arterial hyperæmia is an *accompaniment of inflammation* of the retina and of surrounding ocular structures. *Venous hyperæmia* is seen as a result of pressure, in certain general diseases (especially heart disease), and in a most pronounced form in thrombosis of the central vein.

Anæmia of the Retina may be merely the ocular expression of a *general* condition, or it may be *local*. The latter form may be *acute* or *chronic*. *Acute anæmia* is known as *ischæmia of the retina*; it may result from *occlusion* (embolism of central artery), *compression*, or *spasm* of the retinal arteries. There are extreme *narrowing* of the retinal arteries, *pallor* of the disc, and *blindness*. Such a condition is observed in cholera, and temporarily in migraine. *Quinine poisoning* furnishes an example of *ischæmia* in which some diminution in acuteness of vision and some contraction of the field of vision are permanent. The *chronic* form of anæmia is frequently seen after retinal disease causing *atrophy*; here the blood-vessels become narrower or even changed into slender, empty threads.

Hemorrhages in the Retina often occur *without* any signs of *inflammation*.

Objective Signs. (Fig. 221, Plate XVII).—Retinal hemorrhages *vary in size, shape, and position*; they are found most frequently in the neighborhood of the larger blood-vessels. When situated in the nerve-fibre layer, they have a *striate* or flame-shaped form; when deep, they are *rounded* or *irregular* in outline. Sometimes a large, round extravasation is seen in the region of the macula, between the retina and vitreous; this is known as a *subhyaloid hemorrhage*. Retinal hemorrhages

become *absorbed slowly*. The smaller ones may leave no traces. But more frequently white *spots*, sometimes *pigmented*, indicate their site.

Subjective Symptoms.—*Interference with vision* depends upon the size and particularly the situation of the hemorrhage; if at the macula, vision is much diminished. A *scotoma* results if the retinal tissue has been injured. Subhyaloid hemorrhage causes no permanent change in vision after absorption, since the retina is not involved.

Etiology.—The causes of retinal hemorrhages are: (1) *Injuries*; (2) *local* disease of the *vessels* of the retina and choroid; (3) diseased state of the *blood-vessels*, especially arteriosclerosis and atheroma; this condition is commonly associated with heart and kidney disease, frequently found in old persons, and is often a warning of cerebral apoplexy; (4) disturbances in the *circulation* causing retinal embolism, thrombosis, hemorrhages in the new-born, and after operations; (5) *valvular heart disease* and cardiac hypertrophy; (6) changes in the *composition of the blood* and in the walls of the blood-vessels, seen in anæmia, leukæmia, purpura, scurvy, pyæmia and septicæmia, the malarial fevers, poisons, etc.

Treatment of the etiological factor is indicated. Locally, there is none.

Changes in the Fundus in Arteriosclerosis are of *importance* in general prognosis since the finding of such indicates similar lesions in other parts of the body, especially the brain; ophthalmological evidence may be the first to reveal the existence of this serious vascular lesion. The *fundus* may present any or all of the following changes (Fig. 222, Plate XVII): Increased *tortuosity* and *beaded* appearance of the *blood-vessels*; greater *opacity* of the arteries and widening of the central light-streak; *interruption of continuity* in the *veins* where they are crossed by arteries, and *dilatation* just beyond these points; *white lines* along the course of vessels (*perivasculitis*); retinal *œdema* near disc, along blood-vessels, or scattered in spots; *hemorrhages*.

Embolism of the Central Artery.—Plugging of the central artery of the retina by a *non-infected embolus* causes

PLATE XVII.

FIG. 221.—Hemorrhages in the Retina.

FIG 222.—Changes in the Fundus in Arteriosclerosis.

sudden blindness, which is sometimes unrecognized by the patient, because it is usually *unilateral* and there is *no pain*. The *left eye* is the one generally affected.

Objective Signs.—There are no external signs, but the *ophthalmoscopic* picture is very *characteristic*. Within a few hours, the fundus becomes *pale* and oedematous, *grayish* or even milky; this is most pronounced near the disc and macula and fades out toward the periphery. In the situation of the fovea there is a bright *cherry-red spot* which stands out in marked contrast to the neighboring grayish-white retina; this is due to the red color of the choroid seen through the very thin retina opposite this area. The *arteries* are very *thin* and can be followed only a short distance from the disc; beyond this point they may be *lost* entirely. The veins also contain less than the normal amount of blood. There may be small *hemorrhages*. Pressure upon the eyeball does not produce arterial pulsation, but gives rise to the appearance of broken columns of blood with clear spaces between them.

After a few days, *degeneration* of the retina occurs, and at the end of a few weeks *atrophy* sets in. The oedema subsides, the disc atrophies, and the blood-vessels become shrunken or are represented by white lines.

Subjective Symptoms.—There is *sudden and complete blindness*; even perception of light is lost. Occasionally good central vision is preserved; this is due to the existence of a small macular branch given off from the central artery below its bifurcation, where the embolus usually lodges; but even in such exceptional cases, most of the field is lost.

The foregoing description applies to cases in which the *main trunk* of the central artery is occluded. The embolus may, however, lodge in one of the *branches* of the central artery. In such cases the interference with sight and the changes in the background will be limited to the *area supplied by the occluded branch*. Occasionally the embolus can be seen, but usually its presence is shown by a swelling in the artery, beyond which the vessel is thin or obliterated.

Etiology.—The condition is most frequently due to *valvular heart disease*, less often to atheroma, aneurism, Bright's dis-

ease, and pregnancy. A *thrombus* of the central artery may give rise to the same signs and symptoms as embolism, and a differential diagnosis is difficult or impossible.

Treatment is rarely effective. If the case is seen early, inhalations of *amyl nitrite*, *massage* of the eyeball, and *paracentesis* of the cornea may be employed for the purpose of driving the plug along into one of the smaller branches, where it will give rise to less serious results; in a few cases, such treatment has been beneficial.

Thrombosis of the Central Vein may occur in *old persons* with atheroma and cardiac disease; it also follows *cellulitis of the orbit*. It is one of the causes of hemorrhagic retinitis. It may be *complete* or *partial*. There is *diminution of vision*, either corresponding to the entire field, or if only a branch is affected, to the part of the retina supplied by it. The *veins* are greatly *engorged* and tortuous, the *arteries* very *small*, there are numerous large *hemorrhages*, and indistinctness of the margins of the disc. The condition usually ends in *atrophy* of the retina and disc. There is *no treatment*.

PIGMENTARY DEGENERATION OF THE RETINA, OR RETINITIS PIGMENTOSA.

A *chronic* form of retinitis, which has a constant tendency to become worse, and which consists of *atrophy* of the retina, with migration of *pigment* from the pigment epithelium into the inner layers.

Subjective Symptoms.—*Night blindness* (hemeralopia), *concentric contraction of the field of vision*, *progressive diminution in sight*, terminating in advanced years in *complete blindness*.

In early life there is but slight reduction in the extent of the field with good illumination, and *central vision* is often perfect. But with feeble illumination, the peripheral parts of the retina do not react, and on this account the patient cannot find his way about at night, because the *field is small*. With *increasing years*, the field becomes contracted even with good illumination. Finally, in *advanced life*, *central vision* becomes poor, and gradually *complete blindness* follows.

PLATE XVIII.

FIG. 223.—Pigmentary Degeneration of the Retina.

FIG. 224.—Detachment of the Retina.

Ophthalmoscopic Examination (Fig. 223, Plate XVIII) shows *black spots* in the *periphery* of the fundus. These have the shape of branching cells, like bone corpuscles with connecting processes, and are found especially along the blood-vessels. In the course of years new spots form, and in this way the *pigment circle* gradually approaches the disc. Migration of coloring-matter from the pigment layer of the retina allows the *choroidal vessels* to become plainly *visible*. The *disc and retina* are *atrophied*. The disc has a *yellowish, waxy* appearance. The retinal *arteries* are very *small* and in the *periphery* are represented by mere threads.

There are cases of retinitis pigmentosa in which all the symptoms of this disease are present, and the ophthalmoscope shows all changes *except* the presence of *pigment*, and others in which the pigment is distributed in an *atypical* manner. Syphilitic choroidoretinitis may give a picture similar to that of retinitis pigmentosa, but may be differentiated by the patches of choroidal atrophy.

Occurrence.—The disease affects *both eyes*. It is either *congenital* or develops in *childhood*. It is *hereditary* and is often found in the offspring of consanguineous marriages; not infrequently *other congenital defects*, such as deafness and defective intelligence, are present. It may be complicated with posterior polar cataract and other ocular anomalies.

Treatment is of no avail.

DETACHMENT OF THE RETINA.

Retinal detachment is a *separation of the retina from the choroid*. The name usually refers to a separation by *serum*, but detachment may also occur as a result of subretinal *hemorrhage, exudation, or tumor*.

Subjective Symptoms.—There is more or less complete *loss of vision* in that *part of the field* which is opposite to the detachment, and the appearance of a dark *cloud* before the eye; early symptoms are *metamorphopsia* and flashes of light (*photopsia*). *Central vision* is preserved as long as the *macula* is not included.

Ophthalmoscopic Signs depend upon the degree and extent of detachment. In addition to the other methods, the ophthalmoscope should be used at a distance.

When the detachment is *flat*, the retina appears but slightly changed; it is somewhat *cloudy* and its *vessels* are *dark* and *tortuous*; the variation in *level* of the affected portion can be recognized by the difference in the refraction of a blood-vessel on the separated part.

When the detachment is *steep*, as is generally the case, it is usually found *near the periphery*. It is *at first* limited in extent; it may commence at any part of the retina, but as a result of sinking of the subretinal fluid it is usually found *below*. It tends to *enlarge* and become total, then involving the entire retina. It presents a collection of *grayish*, bluish-gray, or *greenish folds* (Fig. 224, Plate XVIII) with white tops *projecting* a variable distance into the vitreous and *shaking* with movements of the eye. The *blood-vessels* pass over and follow these folds and are therefore very *tortuous*, and *hidden* at places; they appear *prominent* and of a *dark red*, almost black color. Sometimes a rupture can be seen in the separated retina. In the later stages, opacities of the vitreous and cataract are often added. The *rest of the fundus* presents a *normal* picture. Externally the eye appears normal, but *tension* is usually *lowered* and the anterior chamber deepened.

Etiology.—Serous detachments may be due to *injury* or *disease*. Traumatic detachment is usually the result of *blows*; it may follow accidental or operative *wounds*, especially when there has been *loss of vitreous*. When due to disease, it is generally found in *myopia* of high degree, and after disease of the vitreous, iridocyclitis, and iridochoroiditis. In such cases the condition probably results from the *shrinking* of the vitreous, which thus pulls the retina from its attachment. Other forms of detachment are much less frequent and are due to subretinal *hemorrhage*, *exudation*, or *tumor*.

Diagnosis is readily made, but it is sometimes difficult to decide whether the detachment is *serous*, or due to a *tumor* of the choroid (p. 165).

Prognosis is *unfavorable*. The detachment tends to enlarge

and to become total. Even after improvement, *relapses* are the rule, and complete *blindness* is the usual end.

Treatment is sometimes followed by *temporary improvement*, but is rarely productive of lasting benefit. In recent cases, the best treatment is *absolute rest in bed* with a *firm bandage* applied to both eyes, kept up for six to ten weeks. *Potassic iodide*, and daily subcutaneous injections of *pilocarpine* in sufficient dose to produce sweating and salivation (gr. $\frac{1}{12}$) are often tried.

Puncture of the sclera (posterior sclerotomy, p. 183) is frequently resorted to and may be successful, but this is almost always only a temporary gain.

Subconjunctival injections of solution of sodium chloride, either of physiological strength, or five or ten per cent., have proved of value in some cases.

CHAPTER XIX.

DISEASES OF THE OPTIC NERVE.

Anatomy.—The optic nerve may be divided into (1) an *intraocular* portion, the *retina*; (2) an *orbital* portion extending from the eyeball to the optic foramen; and (3) an *intracranial* portion situated between the optic foramen and the chiasm.

The nerve pierces the sclera and choroid a little to the inner side of the posterior pole of the eyeball. At this point the outer layers of the sclera become continuous with the sheaths of the nerve, while the inner layers together with the modified choroid stretch across the foramen, presenting numerous openings for the passage of the separate bundles of the optic nerve; this sieve-like arrangement is known as the *lamina cribrosa*. Here the *nerve fibres lose their medullary layer* and become transparent. Spreading apart before reaching the level of the retina, they leave a funnel-shaped depression at the middle of the disc (Fig. 40), the *physiological excavation*.

The *lamina cribrosa* represents the weakest portion of the layers of the eyeball, and in increased tension is the first to recede. It surrounds the bundles of the optic nerve with fibrous rings of connective tissue, which serve as constricting bands when swelling occurs.

The *orbital portion* of the optic nerve presents a sigmoid curve permitting free movement of the eyeball. The nerve consists of bundles of nerve fibres separated by connective-tissue septa; between these there are *lymph spaces*. The optic nerve is surrounded by *three sheaths* originating from the three envelopes of the brain, and known as the pial, arachnoid, and dural sheaths; between the pial and the dural sheaths is a space, the *intervaginal space*, divided into two parts by the arachnoid sheath. The two spaces thus formed are *lymph spaces*; they are lined by endothelium, and communicate with the corresponding cerebral spaces. Anteriorly, the intervaginal space ends in a blind extremity and the sheaths unite with the sclera.

A short distance from the eyeball, the *central artery* (a branch of the ophthalmic) enters, and the *central vein* emerges; the latter empties into the superior ophthalmic vein or directly into the cavernous sinus.

The *intracranial portion* of the optic nerve is short and flattened. The *optic foramen* forms an unyielding ring which compresses the nerve in inflammation and injury.

Affections of the Optic Nerve comprise (1) *hyperæmia*, (2) *inflammation*, (3) *atrophy*, and (4) *tumors* (very rare).

Hyperæmia or Congestion of the Optic Disc.—

The normal disc varies greatly in color; hence it is often difficult to decide whether the papilla is congested or not. When congestion exists it shows itself in increased redness due to capillary injection, slight blurring and striation of the margins of the disc often limited to a portion of the circumference, and some fulness of the veins.

Such a picture is frequently presented in *eye strain* from hyperopia and astigmatism, *excessive use* of the eyes, or after work with *insufficient* or *excessive light*. It is also found with *inflammations* of the deeper portions of the eyeball. It may be the *incipient* stage of *optic neuritis*.

Inflammation of the Optic Nerve, known as *Optic Neuritis*, is divided into:

1. *Papillitis*, or *Intraocular Optic Neuritis*, in which the *head* of the optic nerve is the part affected, and in which there are marked *visible* changes in the disc.

2. *Retrobulbar Neuritis* affecting the nerve fibres *behind the eyeball*, and in which the changes of the disc are *slight* or *absent*, and the existence of inflammation is often inferred from subjective symptoms.

PAPILLITIS, INTRAOCULAR OPTIC NEURITIS, OR CHOKED DISC.

Symptoms.—There is more or less *disturbance of vision*; it is usually considerable, but it is not always proportionate to the severity of the inflammation as revealed by the ophthalmoscope; there may be complete blindness. The *field of vision* is usually *contracted* peripherally, especially for colors. There may be hemianopsia or scotomata. There is *no pain*, and there are *no external signs*.

Ophthalmoscopic Signs.—The *papilla* appears *swollen* and projecting (Fig. 227), enlarged, of *whitish* or *grayish* color, *striated*, and often presenting *white spots* and *hemorrhages*. Its situation is recognized only by the convergence of the retinal blood-vessels, its *margins* having become *indistinguishable* and extending gradually into the surrounding retina. The retinal *vessels* are altered and are *interrupted* in places;

the arteries are either thin or of normal calibre, the *veins* are greatly distended and exceedingly *tortuous*. The surrounding *retina* is usually *œdematous*, congested, and presents *white patches* and *hemorrhages*. When a large portion of the surrounding retina is involved the affection constitutes *neuro-retinitis* (Plate XIX).

Clinical Forms.—Clinically we may distinguish between two types of papillitis: 1. *Choked Disc*, in which there is marked swelling limited pretty sharply to the disc, with extreme dilatation and *tortuosity of the veins*; *œdema* and *engorgement* are the predominating features (Fig. 226, Plate XIX). 2. *Descending Neuritis*, in which there are less swelling and projection of the disc, less venous fulness and tortuosity, but more *exudation* and considerable *extension* of the latter into the surrounding retina; the picture in these cases points more to *inflammation* (Fig. 225, Plate XIX). No sharp line can, however, be drawn between these two forms, either from the standpoint of pathology or of etiology, and *transition forms* occur frequently.

FIG. 227.—Papillitis (Choked Disc). The upper portion represents the ophthalmoscopic appearances; the lower half, a longitudinal section.

Course.—Though occasionally acute, the course is usually a *chronic* one, extending over a number of months. It is possible for the changes to *subside* and the disc to regain its normal appearance with the preservation of good sight (especially in syphilitic cases). But, as a rule, papillitis is *followed by Postneuritic Atrophy*: The disc becomes white or grayish-white, its margins are sharply defined but irregular, and surrounded by changes in the choroid, while the exudation becomes changed into connective tissue which covers the lamina cribrosa and fills up the physiological cup; the arteries are contracted and frequently bordered by white

PLATE XIX.

FIG. 225.—Neuroretinitis.

FIG. 226.—Papillitis (Choked Disc).

lines, but the veins remain dilated and tortuous (Fig. 231, Plate XX).

Prognosis is always *serious*. The degree of atrophy depends upon the intensity of the preceding neuritis, and determines whether vision finally becomes useful, much impaired, or totally lost.

Etiology.—Papillitis is almost always *bilateral*, but one eye may be affected before the other. The *causes* are: (1) diseases of the brain and its envelopes; (2) syphilis; (3) general diseases; (4) anæmia, either simple, or the acute form due to great loss of blood; (5) diseases of menstruation, pregnancy, and lactation; (6) lead poisoning; (7) heredity; (8) idiopathic (when no cause can be found); and (9) orbital and periorbital affections.

Brain Tumor is the most frequent cause; papillitis occurs in 90 per cent. of such cases and then most commonly assumes the *choked-disc type*. Sometimes the neuritis is the first symptom of brain tumor. The occurrence or degree of papillitis does not depend upon the size or the situation of the tumor. It frequently exists with cerebellar tumors. The neuritis of brain tumor occasionally gives a picture resembling that of albuminuric retinitis with its star-shaped figure at the macula.

Next in frequency comes *meningitis*, especially basilar and tuberculous. In such cases the papillitis is apt to be of the descending neuritis type. Then come *abscess* and *hydrocephalus*.

Syphilis is a frequent cause, and acts either by direct implication or through the development of specific affection in the cranial or orbital cavities.

Acute febrile affections (measles, scarlatina, diphtheria, typhoid, grippe) are occasional causes. *General affections* such as rheumatism, nephritis, and arterial disease are sometimes responsible; also exposure to cold.

Orbital and periorbital affections include inflammations of the orbit, tumors of the orbit and optic nerve, and diseases of the neighboring cavities (sphenoid, ethmoid, frontal, and maxillary). These constitute the examples of *unilateral* cases.

Pathology.—The process consists of an inflammatory swelling, exudation of leucocytes, venous engorgement, hemorrhages and distention of the intervaginal space. The exact mechanism is still unsettled. Numerous hypotheses have been advanced; the most prominent are: (1) that it is due to increased intracranial pressure forcing cerebro-spinal fluid into the intervaginal space of the optic nerve, causing stasis in the region of the lamina cribrosa, compression of the vessels resulting in venous engorgement and œdema (choked disc); (2) transmission of inflammation from the brain along the optic nerve to the papilla; (3) inflammation excited by irritating substances which pass from the cranial cavity to the optic disc.

Treatment should be directed against the cause of the inflammation. Trephining the skull has been followed by improvement. In syphilis, a vigorous course of mercury followed by potassic iodide. Even in non-specific cases mercury and iodide of potassium are often prescribed. Locally, rest of the eyes, shading from light, and sometimes abstraction of blood from the mastoid region.

Retrobulbar Neuritis involves the orbital portion of the optic nerve. Hence, until atrophy makes its appearance, there are few or no changes in the disc, and the diagnosis is made from the disturbance of vision. In most cases there is merely an implication of the papillo-macular fibres of the optic nerve, and consequently the alteration in the field of vision takes the form of a central scotoma, often relative. There are two forms, acute and chronic.

ACUTE RETROBULBAR NEURITIS.

This rather uncommon affection is generally unilateral, occasionally bilateral.

Symptoms.—Neuralgia or headache on the same side, pain in and about the orbit aggravated by movements of the eye, and tenderness on pressing the eye backward into the orbit. With these symptoms there is rapid impairment of sight, progressing in the course of a week to partial or complete blindness. Externally the eye appears normal.

Ophthalmoscopic Signs.—*At first there are no changes ; later there may be slight haziness of the disc, with distention and sometimes diminished calibre of the retinal vessels.*

Course.—The disease runs an *acute* course, and after a month or two, the *sight* usually becomes *normal* ; or the cure is partial, and a *central scotoma* remains ; occasionally it terminates in permanent and total blindness.

Etiology.—Exposure to cold, rheumatism, syphilis, acute infectious diseases, alcohol and other poisons, and extension of neighboring inflammation.

Treatment.—Removal or treatment of the *cause*. Diaphoresis by the use of *pilocarpine* ; *sodium salicylate*. *Potassic iodide*, *mercury*, and *strychnine* are also employed.

CHRONIC RETROBULBAR NEURITIS, TOXIC AMBLYOPIA, TOBACCO OR ALCOHOLIC AMBLYOPIA.

A *chronic* affection of the *orbital* portion of the optic nerve, of *frequent* occurrence, usually attacking *both eyes*, and due in the great majority of cases to excessive indulgence in *tobacco*, *alcohol*, or *both* combined.

Symptoms.—There is gradual *diminution* in acuteness of *sight* ; *foggy vision* ; the patient sees better in the evening and the visual disturbance is *more marked in bright light*. The field of vision presents the normal peripheral boundary, but there is a *central color scotoma* for red and green (Fig. 228), corresponding to the distribution of the papillo-macular fibres of the optic nerve. This color defect is usually *small*, but it may be more extensive and correspond to the limits of the color fields.

The *scotoma* is detected by telling the patient to look steadily at the tip of the surgeon's nose at a distance of about two feet, the other eye being closed, and moving *small pieces of red or green worsted or cardboard* (from 2 to 5 mm. in diam-

FIG. 228.—The Field of Vision in Toxic Amblyopia, showing Central Color Scotoma.

eter) from the periphery toward the point of fixation; when the test object arrives at the seat of the scotoma it will appear *dull or colorless*. This loss of color is more marked on the temporal than on the nasal side of the fixation point, corresponding to the distribution of the papillo-macular bundle of the optic nerve. The color defect is more marked for green than for red. Sometimes the scotoma becomes *absolute* (no perception of light over this area).

Ophthalmoscopic Signs.—*Sometimes there are no changes in the papilla, or merely a slight haze with increased redness. At a later period, there is very often a pallor of the temporal side of the disc.*

Course.—The progress of the disease is *slow*. If poisoning continues, vision becomes more impaired and may be reduced very much. *If the patient stops the use of the toxic material, there is usually gradual improvement and sight is often restored to the normal, with complete disappearance of the scotoma. But in severe cases, there may be some permanent reduction in the acuteness of vision, and the relative scotoma may continue indefinitely.*

Etiology.—The condition results most frequently from *over-indulgence in tobacco* whether in smoking or chewing, occasionally after snuff-taking. The stronger tobaccos used in cigars and pipes are the forms which are most frequently responsible. Certain individuals are more susceptible than others. Impairment of the general health predisposes, as does also the practice of smoking when the stomach is empty. It occurs almost exclusively in *middle-aged or elderly men*. *Alcoholic stimulants* also constitute a very frequent cause; in most cases *both alcohol and tobacco* act together. *Other poisons* which in toxic doses cause a condition resembling tobacco amblyopia are *wood-alcohol* (which is sometimes used to adulterate cheap whiskey, essences, etc.), iodoform, lead, arsenic, the poison of diabetes, bisulphide of carbon, and nitrobenzol.

Pathology.—The process consists of an *interstitial neuritis of the papillo-macular (axial) fibres* of the optic nerve, with subsequent *degeneration* of these fibres and of the *ganglion cells* in the macular region.

PLATE XX.

FIG. 230.—Simple Atrophy of the Optic Nerve.

FIG. 231.—Post-Neuritic Atrophy of the Optic Nerve.

Treatment consists in *abstinence from tobacco and alcohol*; if some stimulant is required, it must be restricted to a small amount with the principal meals. The *general health* should be improved. *Strychnine* is given by mouth or hypodermically in increasing doses, up to the limit of tolerance. *Iodide of potassium* is sometimes prescribed, and used in alternating periods with the strychnine. Large quantities of water taken between meals are also of value.

ATROPHY OF THE OPTIC NERVE.

This affection occurs either as a *primary disease (simple, primary, non-inflammatory, or progressive atrophy)* or *secondary* to some other affection of the nerve or retina (*postneuritic, secondary, or inflammatory atrophy*).

Symptoms.—There are *reduction in the acuteness of vision*, *concentric or irregular contraction of the field* (Fig. 229), first for colors and then for form, diminution in the light sense, sometimes *scotomata*, and *color blindness* (first for green, then for red, then for blue). These symptoms tend to *progress* and end in complete *blindness*.

Ophthalmoscopic Signs differ somewhat in the simple and postneuritic forms:

Simple Atrophy (Fig. 230, Plate XX): The *disc* is *white*, grayish, or bluish-white, its *edges* are *sharply defined* and regular, its *size* is somewhat *diminished*, and it presents a *saucer-shaped excavation* (Fig. 177); the *lamina cribrosa* is often seen very *plainly*. The *minute vessels* of the disc have *disappeared*. The *retinal vessels* may appear normal, but the *arteries* are usually *diminished in calibre*.

Postneuritic Atrophy (Fig. 231, Plate XX): The *disc* is *covered by connective tissue* resulting from the previous neuritis. It has a dense *white* or grayish color, with more or less *ir-*

FIG. 229. — Marked Concentric Contraction of the Field of Vision in Optic-Nerve Atrophy.

regularity and *obscuration* of the *margins*, its *minute vessels* have *disappeared*, and the *lamina cribrosa* is *hidden* by the organized exudation. The *retinal arteries* are *narrow*, enclosed in *white lines*, and the *veins* are enlarged and *tortuous*.

In the secondary atrophy following retinitis pigmentosa the disc has a dirty, grayish-red or yellow, waxy look (Fig. 223, Plate XVIII), the vessels are exceedingly narrow and many disappear entirely.

After a time, the differences in the appearances of simple and postneuritic atrophy become much less marked.

It should be borne in mind that the *disc varies in color in health* and may appear atrophied as the result of *congenital or senile peculiarities*, although vision is normal and the field perfect; hence the diagnosis in many cases cannot be made from the ophthalmoscopic signs alone, especially when these signs are not pronounced.

Etiology.—*Simple atrophy* is frequently due to *spinal diseases*, especially *locomotor ataxia*; it develops in one-third of the cases of this affection and is an early symptom. It is common also in affections of the *brain*: disseminated sclerosis, general paralysis of the insane, and tumors. It is also due to *syphilis*, malaria, diabetes, acromegaly, impaired nutrition, and certain poisons (including wood-alcohol). Occasionally it is hereditary, and in some cases *no cause* can be found. It occurs chiefly in *middle life*.

Secondary atrophy follows *papillitis*, *retrobulbar neuritis*, *retinitis*, *pigmentary degeneration* of the retina, embolism of the central artery, and *glaucoma*. It may result from penetrating wounds of the optic nerve or injury to the nerve due to *fracture* of the orbital canal, following a blow or other violence; in such cases the atrophy does not show itself for a number of weeks, though more or less reduction of vision and contraction of the field result immediately.

Pathology.—The process consists of *increase* in the *interstitial connective tissue* with *atrophy* of the *nerve fibres*.

Prognosis is usually *unfavorable*. *Simple atrophy* generally progresses to absolute *blindness*. In *secondary atrophy* the

prognosis is *better*, and depends upon how much sight has been destroyed by the antecedent inflammation.

Treatment consists in attempting to control the *cause* of the atrophy. For the atrophy itself very little can be done. *Potassium iodide, strychnine, mercury, nitroglycerin*, and *galvanism* are the remedies most frequently employed.

CHAPTER XX.

AMBLYOPIA AND FUNCTIONAL DISEASES OF THE RETINA.

Amblyopia is a *reduction in the acuteness of vision* which cannot be relieved by glasses and which is not dependent upon any visible changes in the eye. The term is sometimes used in a less restricted sense to designate poor sight, even when some changes are found in the eye, as, for instance, toxic amblyopia in which temporal pallor of the disc exists.

Amaurosis is the name applied to *absolute blindness* when unaccompanied by discoverable ocular changes; the use of this term has, however, been extended so as to include all cases of absolute blindness, including those which show ophthalmoscopic or external changes.

Congenital Amblyopia and Amblyopia ex Anopsia.—*Congenitally Defective Vision*, usually affects *one eye* but sometimes both; it is frequently *associated* with high degrees of *hyperopia*, *myopia*, and *astigmatism*. Probably in many of the so-called congenital cases, the amblyopia is really acquired—the errors of refraction have prevented perfect images from being focussed on the retina, and this lack of training has caused amblyopia. The most careful correction of the error of refraction fails to produce normal vision; in young patients, however, the sight can frequently be improved or brought up to the normal after *suitable glasses* have been worn for a time.

Amblyopia ex Anopsia.—Any interference with vision dating from early life, which prevents perfect focussing upon the retina, causes *amblyopia from non-use*; hence the advisability of operating upon congenital and infantile cataracts early. An obstacle to vision beginning after the age of seven or eight years does not usually interfere with the functional activity of the retina.

Unilateral amblyopia predisposes to *squint* by lessening the value of binocular vision. Very commonly amblyopia develops in an eye which has squinted from early life on account of its exclusion from the visual act, the retinal image in this eye being suppressed (p. 337). *Exercise* of such an eye during youth, by forcing it to work while the sound eye is excluded, will frequently *improve* its visual power.

Bilateral congenital amblyopia of high degree is nearly always associated with *nystagmus*.

Hysterical Amblyopia usually occurs in *young girls and women*, occasionally in young persons of the male sex. It is almost always *unilateral*.

Symptoms.—The most constant symptom is a *diminution* in the acuteness of *vision* which frequently amounts to complete *blindness*. The *field* of vision is *contracted* concentrically, both for white and colors; since the retina becomes exhausted rapidly, this limitation may become more marked with each succeeding test during the same examination. The *color fields* have not the same relative areas as with the normal eye; they may be larger than that for white; their order is often *reversed*—*i.e.*, green the largest, red next, and blue the smallest. There may be *scotoma* or *hemianopsia*. A *great variety* of other ocular symptoms may be present, such as photophobia, flashes of light, blepharospasm, corneal anæsthesia, monocular diplopia, ptosis, and changes in the size and shape of images. The *pupillary reflexes* and *ophthalmoscopic appearances* are *normal*.

With these ocular manifestations there are usually *other hysterical symptoms*, especially hemianæsthesia of the affected side. It is sometimes difficult to distinguish between this affection and *malinering*. It sometimes follows injuries (traumatic hysteria) even when these do not involve the eye.

Prognosis is *good*, although the affection may last many months.

Treatment is directed to the *hysterical condition*. *Locally*, *electricity*, *massage*, and hypodermic injection of *strychnine* are productive of good results, probably through *psychic* influences.

Simulated Amblyopia (Malingering).—Patients sometimes *pretend to be blind in one eye* in order to escape military duty or to recover damages for alleged injury; occasionally bilateral blindness is simulated. The *detection* of pretended monocular blindness is usually easy, but occasionally difficult. The following tests may be employed:

Tests.—1. Place a *lighted candle* fifteen or twenty feet in front of the patient and put a *prism* of 6° , base upward or downward, before the sound eye; if the patient sees double it is an indication that the vision is good in both eyes.

2. With the *lighted candle* in the same position, cover up the supposed blind eye. Then produce *monocular diplopia* by moving a 6° *prism*, base upward or downward, until the apex corresponds to the centre of the pupil. Next uncover the blind eye and at the same time move the prism until it covers the entire pupil. If now there is still double vision (binocular diplopia) it is evident that both eyes see.

3. Place a *strong convex lens* (12 D.) before the good eye and a weak concave lens (0.25 D.) in front of the supposed blind eye, and direct the patient to read the distant test types; if he succeeds, it is proof of malingering, since it is impossible for him to see with the sound eye when covered by the strong lens.

It is uncommon for a patient to simulate blindness in *both eyes*, and more *difficult to detect* him in such cases. A diminution in acuteness of vision of both eyes is more frequently feigned than binocular blindness. In such cases, malingering is suspected when there is an *absence of agreement* in the results of the *functional and objective examination* of the eyes, *contradictory statements* regarding the different steps in the functional examination, or contraction of the pupils to light. In rare instances, the pupils react on exposure to light in cases of absolute blindness, the lesion being situated in the visual centres or in the connection between these centres and the corpora quadrigemina (3, Fig. 232). In feigned binocular blindness a *close watch* must be kept on the patient when he thinks he is free from observation, and the following test may be employed: Place a *lighted candle* in front of the patient; hold a

6° prism base outward before one eye; if both eyes see, the one covered by the prism will move inward in order to avoid diplopia; on removing the prism it will move outward, the other eye remaining fixed.

Congenital Color Amblyopia.—Congenital color-blindness occurs in from three to four per cent. of males and in considerably less than one per cent. of females. It generally affects *both eyes*, is often hereditary, and the functions of the eyes are otherwise normal. The cause and pathology are unknown and the defect is incurable. The condition is usually a *partial achromatopsia*—a loss of perception of one or two of the fundamental colors (red, green, and blue). The absence of all appreciation of colors (*complete achromatopsia*) is very rare as a congenital defect, though it is not uncommon in acquired color blindness occurring in optic-nerve atrophy.

Theories of Color Perception and Defects.—A number of theories have been advanced to explain color vision and its derangements. The principal ones are those of Young-Helmholtz, Hering, and Edridge-Green.

(1) *The Young-Helmholtz Theory* assumes that there are three sets of color-perceiving elements in the retina, each of which, if stimulated alone, would give rise to the sensation of one of the three fundamental colors—red, green, and violet; and that all other colors arise from combinations of these. With a defect of one of these primary perceptions, a color will be seen as if composed of the remaining two only. According to the color which is deficient, the patient is said to be *red-blind*, *green-blind*, or *violet-blind*. The more commonly recognized forms are *red blindness*, *green blindness*, and *red-green blindness*.

(2) *The Hering Theory* is that the color sense depends upon chemical changes in three different visual substances in the retina—white-black, red-green, and blue-yellow, by the decomposition and recombination of which substances the sensations of color are produced. According to this theory, color blindness is caused by the absence of one or two of these visual substances.

(3) *The Edridge-Green Theory* supposes that a photograph is formed in the retina by decomposition of the visual purple in the rods; this chemically stimulates the ends of the cones, causing a visual impulse to be transmitted through the optic nerve fibres to the brain. It assumes that this impulse differs in quality according to the wave-length (color) of the rays of light producing it, and that there is a special centre in the brain to distinguish these differences. Edridge-Green describes two distinct kinds of color blindness: (a) an inability to perceive certain rays of the spectrum, the latter being shortened at one or both ends, *e.g.*, a red-blind person will say that he sees no light at all when shown a pure red light by means of a lantern; (b) a defect in the power of distinguishing differences of wave-length (color) of light, though the light itself is perceived.

Tests for Color Vision are particularly useful in the examination of employees in certain occupations in which perfect color perception is essential. This is of especial importance in the *railway and steamship service*, in which the most commonly used *signals* are *red and green*, the colors in which most color-blind persons are defective.

The most common and convenient method of examination is *Holmgren's Test* with a large assortment of *colored worsteds*. This collection consists of (1) certain colors called "*test colors*" (a *pale green*, a *light pink*, and a *bright red*), (2) lighter tints and darker shades of these colors ("*match colors*") and (3) "*confusion colors*" (yellow, brown, gray, drab, fawn, mauve, pale blue, etc.), hues which experience has shown that the color-blind individual will select as matching the test colors, but which appear entirely different to the normal eye. The test must be made in good daylight.

The pale green sample is given to the individual and he is required to select colors which match the test sample; if he does this correctly, he has normal color sense. If he not only selects similar colors but also confusion colors, and in addition shows a certain hesitancy, his color sense is defective.

Next a pink skein is selected and the person examined is asked to match this. If besides similar skeins he also selects

blue or violet, he is *red-blind*; if he selects green or gray, he is *green-blind*.

Finally, the bright-red test skein is given to the individual for matching. If, besides reds, he chooses green and brown colors darker than the red, he is *red-blind*; if he selects shades of those colors lighter than the red, he is *green-blind*.

Edridge-Green uses four test colors (orange, violet, blue-green, and red) in skeins of colored wool and in a lantern with colored glasses. The person examined is required to name and to match the four test colors.

The skeins of colored worsteds have been collected upon a stick (*Thomson's Test*) and numbered, so as to facilitate testing of employees and the record of their examinations. Railroad and steamship men are often tested by *Color Test Lanterns* (Thomson's, Williams', Edridge-Green's) in which colored discs are slid in front of an aperture; over these smoked glass can be placed, so as to imitate the appearance of signal lights under all conditions of weather and atmosphere.

The *spectroscope* is also employed for testing the color sense.

Acquired Color Blindness is often found as a symptom of *diseases of the retina and optic nerve*. It is generally present in *optic-nerve atrophy* when vision is markedly impaired.

Colored Vision is occasionally complained of by patients with or without changes in the retina. The most frequent form is *red vision* (*Erythropsia*) after cataract extraction. Rarely green, blue, yellow, or white vision is met with.

Amblyopia and Amaurosis from Various Causes.

—Besides the forms of amblyopia already described, there are others, of less frequent occurrence, due to uræmia, reflex irritation, malaria, and quinine. A considerable number of *drugs* are occasionally responsible for more or less complete amblyopia.

Uræmic Amblyopia has been described on p. 220.

Reflex Amblyopia, due to reflex irritation, is rare and of rather doubtful occurrence, except in the case of the teeth, irritation from which has been found responsible for amblyopia in occasional instances.

Malarial Amblyopia has been observed in malarial diseases. It affects one or both eyes, lasts some hours or days, and

usually disappears completely as a result of the use of anti-periodics.

Quinine Amblyopia or Amaurosis occurs after large quantities of quinine have been taken, occasionally with moderate doses in susceptible individuals. Besides other symptoms of cinchonism there are more or less complete *blindness*, often noticed suddenly, *contracted fields*, dilated pupils, and marked *pallor of the disc*, with extreme contraction of the *retinal vessels*. The condition is due to *spasm* of the *retinal vessels* causing *anæmia* of the fundus, *degeneration* of the ganglion cells and nerve fibres of the retina, and later *atrophy* of the optic nerve. After a time, *central vision is restored* completely or partially, and the field widens, but rarely regains its full extent. *Treatment* consists in *discontinuing the drug*, inhalations of *amyl nitrite*, the use of *nitroglycerin*, *strychnine*, *digitalis*, and the bromides.

Night Blindness (*Hemeralopia*, sometimes called *nyctalopia*) is a condition in which the *sight is good by day* or with good illumination, but more or less *deficient at night* or with reduced illumination. It is a symptom of certain forms of *retinitis*, especially *retinitis pigmentosa*, but it also occurs without ophthalmoscopic changes. The latter form of diminished light sense is caused by *anæsthesia of the retina*; it usually coexists with xerosis of the conjunctiva and is dependent upon the same cause—diminished ocular nutrition due to a debilitated state of the system, such as exists in starvation, profound anæmia, scurvy, and the like. The affection usually disappears with improvement of the general health by good and sufficient food, tonics (cod-liver oil, iron), and the use of dark glasses.

Day Blindness (*Nyctalopia*, sometimes called *hemeralopia*) is the name given to a condition in which the *sight is better at dusk* or in *feeble illumination* than in bright light. This symptom is found in *toxic amblyopia* and with *central scotoma* in general. In cases in which there are central opacities of the lens or cornea, the patient sees better in reduced illumination because the dilated pupil permits vision through the peripheral clear portion of the cornea and lens.

HEMIANOPSIA.

Connection between the Retinæ, the Fibres of the Optic Nerves and Tracts, and the Cerebral Cortex (Figs. 161 and 232; also Plate XXI).—Familiarity with the course of the optic-nerve fibres from the eye to the cortex is of great practical value in

the localization of various lesions causing defects in the field of vision.

The *optic nerves* terminate at the *chiasm*, which lies in the optic groove on the body of the sphenoid bone, where they *semi-decussate*; from the posterior border of the chiasm they are continued backward as the *optic tracts*. The *optic tracts* pass outward and backward, winding around the *crura cerebri* to the *primary optic ganglia*—the external geniculate bodies, the anterior corpora quadrigemina, and the pulvinar of the optic thalami (*POG*, Figs. 161 and 232). Here the fibres divide into two portions: (1) a smaller part passing to the *nuclei of the oculomotorius* and presiding over the reflex action of the *pupils* and the movement of the *ocular muscles*; and (2) a larger bundle, composed of visual fibres, which transfers its impulses (Fig. 161) to other fibres which carry the visual impressions to the

FIG. 232. — Schematic Representation of Visual Paths. L, Left eye; R, right eye; TL, temporal field of left eye; NL, nasal field of left eye; NR, nasal field of right eye; TR, temporal field of right eye; ON, optic nerve; C, chiasm; POG, primary optic ganglia; OMN, oculomotor nuclei; O, occipital lobe; OR, optic radiations. Division of fibres at 1 causes complete blindness of the left eye and loss of direct pupillary reaction; at 2, right homonymous hemianopsia with loss of reaction of the pupil when the left halves of the retinae are illuminated; at 3, right homonymous hemianopsia with preservation of the reaction of the pupil when the left (and right) halves of the retinae are illuminated; at 4, bitemporal hemianopsia; at 5, left nasal hemianopsia.

cortex; the latter fibres pass through the posterior portion of the internal capsule, then form the *optic radiations* or fibres

of Gratiolet, and end in the cortical ganglion cells of the mesial surface of the *cuneus* and the parts surrounding the *calcarine fissure*; this portion of the occipital lobe is known as the *visual area of the cerebral cortex* (O, Fig. 232).

In the ganglion cells of the visual area, an excitation in the optic-nerve fibres is changed into a sensory perception (sight) or into permanent changes (memories, optical memory pictures). After destruction of this area, excitation of the optic-nerve fibres either fails to arouse visual sensation of any kind (*blindness*) or fails to summon forth any recollection of objects or circumstances acquired through previous education; in the latter case, objects are seen but not recognized (*psychical or cortical mind-blindness*).

Each retina is supplied by optic-nerve fibres passing to *both sides of the brain*. Each *optic nerve* is composed of an *external* set of fibres derived from the outer or temporal half of the retina, and an *internal* set derived from the inner or nasal half of the retina. In the axis of the optic nerve is found a special set of fibres which pass to the *macula* and the space between it and the disc. These macular fibres, when they reach the eyeball, are collected into a sector corresponding to the outer third of the disc, the apex directed toward the centre and the base toward the margin of the papilla. The *external or temporal fibres* are continued along the lateral part of the chiasm and tract and pass to the primary optic centre of the *same side*. The *inner fibres*, derived from the nasal half of the retina, pass into the chiasm and *decussate*; they are continued in the tract of the *opposite side*, thus passing to the side of the brain opposite to the eye which they supply.

The *chiasm* presents laterally the direct or temporal fibres of both eyes, and in its centre, the decussation of the inner or nasal fibres of both retinae. Consequently, the decussation in the chiasm is not complete but partial—a *semi-decussation*.

Each optic tract contains fibres from both eyes. The right optic tract consists of non-decussating fibres from the right (temporal) half of the retina of the right eye, and decussating fibres from the right (nasal) half of the left eye. Hence the *right halves of both retinae* and thus the *left halves of both*

PLATE XXI.

FIG. 233.—Schematic Representation of the Visual and the Pupillary Paths.

visual fields are connected with the *right tract* (Plate XXI). It follows, therefore, that the visual impulse excited by objects placed to the left of the median line passes to the cortex of the right hemisphere by means of the right optic tract; and that the perception of all objects placed to the right of the median line is conveyed by the left optic tract to the cortex of the left hemisphere.

Hemianopsia.—This arrangement of fibres in the chiasm explains the occurrence of a form of visual disturbance known as hemianopsia (*hemianopia*, *hemiopia*) by which we mean the *loss of vision for corresponding halves or sectors of the visual fields*. If a lesion interrupts the continuity of the right optic tract, the right cortical visual area, or any portion of the visual path between these parts, there will be blindness of the right halves of both retinæ; as a result, the left halves of the fields of vision of both eyes will be lost, and only objects which are placed to the right of the median line will be perceived. This is known as *homonymous or lateral hemianopsia*, and in this particular case the condition is called left homony-

FIG. 234.—The Fields of Vision in Right Homonymous Hemianopsia.

mous hemiopia, because the left halves of the fields of vision are wanting. Homonymous hemianopsia (Fig. 234), therefore, always points to a lesion situated in the visual path or cortex on the *central side of the chiasm* and upon the *same side as the blind halves of the retinæ*. It is the commonest form of hemianopsia.

If a lesion extends antero-posteriorly through the chiasm it

will destroy all the decussating fibres which supply the inner or nasal halves of both retinæ, and there will be a loss of vision in the outer or temporal halves of the field of both eyes, a condition called *bitemporal hemianopsia* (4, Fig. 232). It is seen in acromegaly.

If a lesion attacks each side of the chiasm, it will destroy the non-decussating fibres which come from the temporal halves of the retinæ, and will, therefore, cause a loss of the nasal or inner half of the field of vision of each eye; this is known as *binasal hemianopsia*. Bitemporal and binasal hemianopsia are known as *crossed hemianopsia*. These forms are rare, as will be inferred when the situation of the lesion necessary to produce them is considered; it is doubtful whether binasal hemianopsia ever occurs. Another rare form of hemianopsia is a *altitudinal* (inferior or superior)—when the upper or the lower half of each field is wanting.

Hemianopsia is said to be *complete* when there is a *symmetrical absence* of the *entire half* of the field of vision. It is *incomplete* when there is an absence of a *small portion* or *sector* occupying a *symmetrical* position in the visual fields of the two eyes; the lesion then involves only a portion of the fibres of a visual tract or cortical visual area.

Even in cases of complete hemianopsia, the line between the absent and the preserved portion of the field seldom extends through the fixation point, the portion of the field corresponding to the *macula* being usually *preserved*. When both halves of the fields are lost successively (double homonymous hemianopsia), there will be blindness except at the situation of these macular fibres. This occurrence has been explained by supposing (1), that the macula receives fibres from both hemispheres, and (2), that the cortical centre for the macula receives a special and abundant blood supply.

Hemianopsia is known as *absolute* when there is loss of light, form, and color sense, and *relative* when only the color sense or both the color sense and form sense are destroyed over the symmetrically defective areas. The latter form is also known as *hemiachromatopsia*; it is believed by some to indicate the existence of separate cortical centres for color, form,

and light perception, by others to point to a lesion of less intensity than that which causes absolute hemianopsia.

Complete blindness in one eye only is always due to a lesion situated *in front of the chiasm*. The same applies to *scotomata*, which are defects in the visual field of one eye (p. 15), or non-symmetrical defects in the fields of both eyes; when central, they indicate an involvement of the papillo-macular sector of the optic nerve.

The Hemiopic Pupillary Reaction (Wernicke) may be of value in determining whether a lesion causing homonymous hemianopsia is situated *behind* or *in front* of the *primary optic ganglia*. If behind this point, the pupillary light reflex will be preserved; if in front of these ganglia (in the optic tract) it may be diminished when the blind half of the retina is illuminated (Fig. 161). This test is very difficult to apply in a conclusive manner.

Scintillating Scotoma (*Transient Hemianopsia*) is a form of temporary blindness generally associated with *migraine* and probably due to a *circulatory disturbance* in the occipital lobe. The *attack* begins with a central *dark spot* before both eyes, which spreads by *scintillating* and colored zigzag lines until there is a considerable *gap in the field*, often hemianopic. Accompanying the attack there are *headache*, general malaise, vertigo, and sometimes nausea and vomiting. The attacks vary in frequency and last about fifteen minutes, after which the amblyopia disappears entirely. The affection occurs after *excessive* mental or physical *exertion* and following marked *eye strain*. Unless associated with paralysis, aphasia, or other symptoms of cerebral trouble, it is *not of serious import*. *Treatment* consists in attention to the *general health*, *correction of eye strain*, avoidance of *fatigue* of any kind, and the use of remedies suited to *migraine*.

CHAPTER XXI.

GENERAL OPTICAL PRINCIPLES.

From a luminous point, rays of light pass out in straight lines in every plane and in every direction; the lines of direction are called *rays*. These travel with a rapidity which diminishes with the density of the medium traversed. The amount of *divergence* of the rays of light falling on a given area is inversely proportionate to the distance of the luminous source; the nearer this point, the more divergence. When proceeding from a point distant *twenty feet or more*, the divergence of rays is so slight, that for practical purposes we may assume them to be *parallel*.

When a ray of light meets an *opaque* body, it is either *absorbed* or *reflected*. When it meets a *transparent* medium, some of it is absorbed and reflected, but the greater part *traverses* the medium, being *deflected* in its course; this bending is called *refraction*.

Reflection occurs from any polished surface (mirror)—plane, concave, or convex. The ray striking the mirror is called the *incident ray* (*IB*, Fig. 235); that returning from the mirror, the *reflected ray* (*BR*, Fig. 235).

Fig. 235.—Reflection by a Plane Surface.

Laws of Reflection: (1) The angle of reflection is equal to the angle of incidence. (2) The reflected and incident rays are both in a plane perpendicular to the reflecting surface. In Fig. 235 *IB* is the incident ray on the reflecting surface *AC*, *BR* the reflected ray, and *PB* the perpendicular. The angle

of incidence, *IBP*, is equal to the angle of reflection, *PBR*. *IB*, *PB*, and *BR* lie in the same plane.

Reflection by a Plane Mirror.—The image is formed at a distance behind the mirror equal to the distance of the object in front of it; it is a *virtual* image, *erect*, and of the *same size* as the object. In Fig. 236, *O* is the object, *I* the image, and *E* the eye of the observer. The image of the candle *O* is found behind the plane mirror *MM*; the observer's eye *E* receives the rays from *O* as if they came from *I*.

Reflection from a Concave Mirror.—A concave surface may be considered as made up of a number of plane surfaces inclined toward one another. *Parallel rays* falling on a concave mirror are *reflected as convergent rays* which meet on the axis of the surface at a point called the *principal focus* (Pf , Fig. 237); the latter is midway between the mirror and its optical centre C . The distance of the principal focus from the mirror is called the *focal length* of the mirror.

The Position of an Image formed by a concave mirror varies with the distance of the object from the mirror. If the object be placed at the principal focus, Pf , the reflected rays are parallel to each other and to the axis of the mirror. If the object be placed at the centre of concavity C , the reflected rays return along the same lines. If the object is beyond the centre, at CF , the reflected rays focus between the centre and the principal focus at cf ; and conversely, if the object be moved between the principal focus and

FIG. 236.—Formation of Image by a Plane Mirror.

FIG. 237.—Reflection by a Concave Mirror.

the centre, at cf , its focus will be beyond the centre, at CF ; these two points, CF and cf , bear a reciprocal relation to each other and are known as *conjugate foci*; the nearer the object approaches the principal focus, the greater the distance at which the reflected rays meet. If the object

be placed nearer the mirror than the principal focus, at X , reflected rays will be divergent and never meet; if, however, these divergent rays are continued backward, they will unite at a point, Vf , behind the mirror; this point is called the *virtual focus*, and an observer placed in the path of the reflected rays will receive them as though they came from this point.

It follows, therefore, that concave mirrors produce an enlarged, erect, and virtual image if the object is placed nearer than the principal focus; no image of an object placed at the principal focus; an enlarged, inverted, real image if the object is placed between the principal focus and the centre; an inverted image of the same size when placed at the centre; and a smaller, inverted, real image if the object is placed beyond the centre.

FIG. 238.—Reflection by a Convex Mirror.

Reflection by a Convex Mirror.—

Parallel rays falling on a convex surface are reflected *divergent* and hence never meet; but if prolonged backward a *negative image* is formed at a point called the *principal focus* (Fig. 238, F). The image is always *virtual*, *erect*, and *smaller* than the object, independent of

the position of the object before the mirror.

Refraction is the *deviation* in the course of rays of light in passing from one transparent (dioptric) medium into another of different density (*refracting medium*). The ray which falls *perpendicular* to the surface separating the two media is *not refracted* but continues in a straight course (Fig. 239, PP).

In passing from a *rarer* to a *denser* medium, a ray is refracted *toward the perpendicular* to the refracting surface; in passing from a *denser* to a *rarer* medium, the ray is refracted *away from the perpendicular*. In Fig. 240, the incident ray IR , in passing from a rarer medium (air) into a denser medium (glass), is refracted toward the perpendicular PP ; in passing from a denser to a rarer medium, the emergent ray ER is refracted from the perpendicular PP . The ray continues in a line parallel to its original course, but has suffered lateral deviation. The angle formed by the incident ray with

FIG. 239.

FIG. 240.

FIG. 239.—Passage of a Perpendicular Ray Through a Transparent Medium.

FIG. 240.—Refraction by a Transparent Medium with Parallel Surfaces.

the perpendicular, IRP , is known as the *angle of incidence*; the angle formed by the emergent or refracted ray with the perpendicular, PER , is known as the *angle of refraction*.

Index of Refraction.—The *relative density*, or the comparative length of time occupied by light in travelling a definite distance in different transparent media is known as the index of refraction. Air being taken as 1.00, the index of refraction of water is 1.33, of the cornea 1.33, of the lens 1.40, of crown glass 1.5, of flint glass 1.6, and of diamond 2.50.

PRISMS.

A prism is a piece of glass or other refracting substance bounded by *plane surfaces inclined toward each other* (Fig. 241). The angle formed by the two surfaces is called the *refracting angle* of the prism (BAC), the thin edge where the intersecting surfaces meet is known as the *apex* (A), and the opposite thick portion as the *base* (BC).

Refraction by a Prism.—

Rays of light passing through a prism are *bent toward the base*. In Fig. 241, the incident ray IR is refracted toward the perpendicular PR , at R , and assumes the direction RR in the prism; on emerging, it is refracted away from the perpendicular and continues as RE toward the base of the prism. To the eye placed at E , the ray RE seems to come from X ; hence *an object seen through a prism appears displaced toward the apex*. A prism has neither converging nor diverging power and therefore has no focus and cannot form an image; rays that are parallel before entering the prism are parallel on emerging (Fig. 242).

FIG. 241.—Refraction by a Prism.

FIG. 242.—Passage of Parallel Rays Through a Prism.

image; rays that are parallel before entering the prism are parallel on emerging (Fig. 242).

The Numbering of Prisms.—The *strength* of a prism is expressed (1) in degrees, (2) in centrad, and (3) in prism-

diopeters. In the first method (*degrees*), which in spite of certain faults is the one most generally used, the value of the prism corresponds to the *refracting angle* (geometrical angle) and is expressed: Prism 1° , 2° , 10° , etc. A *centrad* corresponds to a deviation, the arc of which is $\frac{1}{100}$ of the radius, and is expressed 1∇ , 2∇ , 10∇ , etc. The *prism diopter* is a deviation, the tangent of which is $\frac{1}{100}$ of the radius, and is expressed: 1 P. D. or 1Δ , 2 P. D. or 2Δ , etc. Within the limits of common use, the three scales can practically be considered alike.

The Position of a Prism when placed in front of an eye is indicated by the *direction of its base*; "base out" means that the thick part of the prism is toward the temple; the base may be up, down, in, or out.

The Uses of Prisms: (1) To counteract the effects of muscular paralysis or insufficiency; (2) for the exercise of weak muscles; (3) to test the extent to which the eyes can be deviated from parallelism; (4) as a test for heterophoria; (5) for detecting simulated blindness.

LENSES.

A lens is a transparent *refracting medium*, usually made of glass, in which one or both surfaces are *curved*. There are two kinds: *spherical* and *cylindrical* lenses.

FIG. 243.—The Relation of the Surfaces of Lenses to Spheres. 1, Plano-convex; 2, biconvex; 3, convex meniscus; 4, plano-concave; 5, biconcave; 6, concave meniscus.

Spherical Lenses are so called because the curved surfaces are segments of spheres (Fig. 243); such lenses refract rays of light equally in *all meridians* or planes. There are two kinds of spherical lenses, *convex* and *concave*.

Convex Spherical Lenses are formed of *prisms* with their *bases together* and toward the centre (Fig. 244, A); they are therefore *thick at the centre* and thin at the edge. They are known as *con-*

verging, magnifying, positive, and *plus* lenses, and denoted by the sign $+$. They have the power of *converging* parallel rays and of bringing them to a *focus* (Fig. 247). There are three different forms: (1) *Plano-convex*, one surface plane, the other

FIG. 244.—The Formation of Lenses by Prisms.

FIG. 245.—Convex Lenses.
1. Plano-convex; 2, biconvex; 3, convex meniscus.

FIG. 246.—Concave Lenses.
1. Plano-concave; 2, biconcave; 3, concave meniscus.

convex (1, Fig. 245); (2) *biconvex* or double convex, both surfaces convex (2, Fig. 245); (3) *concavo-convex* (*convex periscopic*, convex or converging *meniscus*), one surface convex, the other concave—the former having the shorter radius of curvature (3, Fig. 245). The *periscopic* lens (whether $+$ or $-$) diminishes spherical aberration and enlarges the field of vision.

Concave Spherical Lenses are formed of *prisms* with their *apices together* and toward the centre (Fig. 244, B); they are therefore *thin at the centre* and thick at the edge. They are known as *diverging*, reducing, negative, or *minus* lenses, and denoted by the sign $-$. Rays of light after passing through

FIG. 247.—The Action of a Convex Lens on Parallel Rays.

FIG. 248.—The Action of a Concave Lens on Parallel Rays.

a concave lens are rendered *divergent*; if prolonged backward they form an image on the same side as the object (Fig. 248). There are three different forms: (1) *Plano-concave*, one surface plane, the other concave (1, Fig. 246); (2) *biconcave* or

double concave, both surfaces concave (2, Fig. 246); (3) *convexo-concave* (*concave periscopic*, concave or diverging *meniscus*), one surface convex and the other concave, the latter having the shorter radius of curvature (3, Fig. 246).

The Action of Spherical Lenses.—Since spherical lenses are formed of prisms with their bases (convex) or apices (concave) in apposition, and since rays in passing through a prism are refracted toward its base, it follows that *convex lenses cause convergence* (Fig. 247), and *concave lenses produce divergence* of rays (Fig. 248).

A line passing through the centre of the lens (optical centre or nodal point, *O*, Fig. 249) at right angles to the surfaces of the lens is called the *principal axis* (*AB*, Fig. 249). A ray passing through this axis (*axial ray*) is *not refracted*; all other rays suffer more or less refraction. Rays passing through the optical centre of a lens, but not through the principal axis (*secondary rays*) are slightly deviated, but emerge in the same direction as they entered

FIG. 249.—Principal and Secondary Axes of a Convex Lens.

(*CD* and *EF*, Fig. 249); the deviation in thin lenses is so slight that practically they may be considered as straight lines and are called *secondary axes*.

Foci of a Convex Lens.—The point to which rays converge after refraction by a convex lens is called its *focus*. The *principal focus* is the *focus* for *parallel rays* (*F*, Fig. 250); the distance of this point from the optical centre is called the *focal distance* of the lens (*XF*, Fig. 250). Since the course of a ray passing from one point to another is the same, independent of the direction, it follows that rays from a luminous point placed at the principal focus will emerge as parallel after passing through the lens.

FIG. 250.—The Principal Focus of a Convex Lens.

In Fig. 250, the rays ABC strike the surface of the lens at LMN ; the axial ray B strikes the lens at M perpendicular to its surface and consequently continues in a straight line to F . The ray A strikes the lens obliquely at L and is bent toward the perpendicular of the surface of the lens at that point, shown by the dotted line PR ; on leaving the lens obliquely at S it is deflected away from the perpendicular RT , being directed to F where it meets the axial ray BF . The ray C is refracted in a similar manner; it is bent upon entering the lens at N and rendered additionally convergent when emerging from the lens, and finally it meets the other rays at F . If, in this same illustration, the rays proceed from F , the principal focus, they emerge parallel (LA , MB , NC) after passing through the lens.

Conjugate Foci of a Convex Lens.—Conjugate foci are *interchangeable foci* in which the image can be replaced by the object and the object by the image. When divergent rays (*i.e.*, rays coming from a point nearer than twenty feet) proceed from a point beyond the principal focus, they will meet at a point beyond the principal focus on the other side of the lens. The more distant the luminous point, the nearer the principal focus (on the other side of the lens) will the rays be focussed. If the luminous point is situated at a distance

FIG. 251.—Conjugate Foci of a Convex Lens.

equal to twice the focal length of the lens, the rays will focus at the same distance on the opposite side. These are conjugate foci.

In Fig. 251, the rays diverging from O and passing through the lens converge at I ; if they diverge from I , they would return in the same path, and meet at O ; the points O and I are conjugate foci. In the preceding example the conjugate focus is *positive* or *real*.

Virtual or Negative Focus of a Convex Lens.—When rays diverge from some point between the lens and its principal

focus (Fig. 252, *O*), they will continue divergent after refraction, but less so than before entering the lens; if prolonged backward they will meet at a point (*I*, Fig. 252) on the same side of the lens from which they diverged; this point is a *negative* or *virtual* focus.

FIG. 252.—Virtual Focus of a Convex Lens.

Foci of a Concave Lens.—After passing through a concave lens, rays of light, whether

originally parallel or divergent, are always *divergent* and the *focus* is, therefore, always *negative* or *virtual*; it is found by

FIG. 253.—Real, Inverted and Reduced Image Formed by a Convex Lens.

continuing these divergent rays backward until they meet at a point (Fig. 248).

Formation of Images.—The *image* of an object formed by a lens is a *collection of foci*, each corresponding to a point in the

FIG. 254.—Real, Inverted and Enlarged Image Formed by a Convex Lens.

object. Such images are either *real* or *virtual*. A *real image* is formed by the *meeting of rays*; it can be projected on a screen. A *virtual image* is formed by the *prolongation back-*

ward of diverging rays until they meet at a point; it can only be seen by looking through the lens.

To find the position and size of an image formed by a lens, it is necessary to obtain the conjugate focus of each extremity of the object: Two lines are drawn from each of these points, one parallel to the axis of the lens and then through the principal focus, and the other through the optical centre; the image will be formed at the point where these rays intersect (Figs. 253, 254, 255).

In Fig. 253, AB is the object, O is the optical centre of the lens, and PF its principal focus. From A , two rays are drawn, one parallel to the axis of the lens and then through the principal focus PF , and a secondary ray through O ; the image of the point A is formed at a , where these two lines intersect. The conjugate focus of B is found in the same manner.

The relation in size between image and object depends upon their respective distances from the optical centre of the lens.

In Fig. 253, the object is placed at a greater distance than twice the principal focus, hence the image is real, inverted, and smaller. If the object is situated at exactly twice the distance of the principal

FIG. 255.—Virtual Image Formed by a Convex Lens.

focus, the image will be real, of the same size, and inverted. If the object is situated just beyond the principal focus, the image will be real, enlarged, and inverted (Fig. 254). If the object be placed at the principal focus, the rays will be parallel after refraction and no image will be obtained. If the object be nearer than the principal focus, the rays will be divergent after passing through the lens (Fig. 255) and no real image will be formed; but by projecting these rays backward they would meet, and an eye placed at PF , Fig. 255, will receive the rays from AB as if they came from ab ; the image will be enlarged, erect, and

virtual; it is on the same side of the lens as the object, and is seen only by looking through the lens, which acts as a *magnifying glass*.

Images formed by concave lenses are always virtual, erect, and smaller than the object; they are seen only by looking through the lens, which acts as a *reducing glass* (Fig. 256).

FIG. 256.—Virtual Image Formed by a Concave Lens.

Cylindrical Lenses.—A cylindrical lens or cylinder is a *segment of a cylinder parallel to its axis* (Fig. 257). Cylinders are divided into *convex* and *concave*.

Light passing through a cylinder *in the plane of its axis* is *not refracted* and behaves exactly as though passing through a plate of glass with parallel sides; in this direction, the surface of the lens is straight. But when light passes through in a *plane opposite* or *perpendicular to the axis* of a cylinder, the rays are rendered *convergent* or *divergent*, according as the cylinder is convex or concave; in this direction the surface of the lens is curved. Parallel rays of light after refraction by a cylinder are focussed in a straight line which corresponds to the axis of the cylinder (Figs. 258, 259). A spherical lens refracts equally in all planes; a cylindrical lens does not refract in the axial plane, but all other rays are refracted, those the most which pass at right angles to its axis. It is necessary to *indicate the direction of the axis of a cylinder*; in the lenses of the trial case, used for the estimation of the refraction of the eye, this is done by a short linear scratch on the lens at its margins or by having a portion of the surface on each side ground parallel to its axis (Fig. 261).

FIG. 257.—The Construction of a Convex and a Concave Cylindrical Lens from a Cylinder.

The Numeration of Lenses.—The *strength* of a lens refers to its power of bringing parallel rays to a focus—*i.e.*, its *refrac-*

tive power ; this is indicated by its *principal focal distance*, the interval between the optical centre of the lens and the principal focus. The shorter this distance, the stronger the lens; the greater the principal focal distance, the weaker the lens. *The strength of a lens is the inverse of its focal distance.*

There are *two systems of numbering lenses*: (1) The Inch, and (2) the Metric or Dioptric.

In the *Inch System*, the *unit* is a strong lens which brings parallel rays to a focus at one inch; this is known as $\frac{1}{1}$ or 1, and every other lens is a *fraction* of this unit, in which the

FIG. 258.—The Action of a Convex Cylindrical Lens upon Parallel Rays.

FIG. 259.—The Action of a Concave Cylindrical Lens upon Parallel Rays.

focal distance in inches forms the *denominator*. For instance, $\frac{1}{4}$ has a focal distance of 4 inches, $\frac{1}{10}$ of 10 inches, $\frac{1}{40}$ of 40 inches. Such lenses are also expressed by the terms No. 4, No. 10, No. 40, indicating their focal strength. This system, though very simple, is open to the objections (1) that the inch varies in length in different countries, (2) the lack of uniform intervals, and (3) the inconvenience of adding or subtracting vulgar fractions in practical work.

The *Metric or Dioptric System* accepts as its *unit* a lens which has its principal focus at *one metre* distance ($39\frac{1}{2}$ English inches, in round numbers 40 inches); this lens is known as 1.00 *dioptr* (abbreviated D.). Every lens is numbered by

its strength in *whole numbers* and in *decimal fractions* (0.25, 0.50, 0.75). A lens which has twice the strength of the unit is known as 2 D.; its focal distance is one-half of a metre. If the lens has a strength four times that of the unit, it is called 4 D., and its focal distance is one-quarter of a metre. If ten times as strong as the unit, it is known as 10 D., and its focal distance is one-tenth of a metre. If one-quarter, one-half, or three-quarters as strong as the unit, it is known

FIG. 260.—Spherical Lens from Trial Case.

FIG. 261.—Cylindrical Lens from Trial Case.

as 0.25 D., 0.50 D., or 0.75 D. respectively. In this system the number of the lens does not express its focal distance; but the focal distance in centimetres is obtained by dividing 100 cm. by the number of the lens; for example a 2 D. lens has a focal distance of $\frac{100}{2} = 50$ cm.; a 5 D. lens has a focal distance of $\frac{100}{5} = 20$ cm. *The dioptric system is the one now universally adopted.*

To convert the focal distance in inches into the focal distance in diopters, or vice versa, divide the number 40 by the number of inches or diopters expressed. For example, 8 D. = $\frac{40}{8} = 5$ inches = $\frac{1}{5}$; 0.50 D. = $\frac{40}{0.5} = 80$ inches = $\frac{1}{80}$; $\frac{1}{20}$ (twenty inches) = $\frac{40}{20} = 2$ D.; $\frac{1}{10}$ (ten inches) = $\frac{40}{10} = 4$ D. The following table gives the commonly employed (approximate) equivalents in the inch and the dioptric systems:

COMMONLY EMPLOYED (APPROXIMATE) EQUIVALENTS OF LENSES
NUMBERED IN THE DIOPTRIC AND INCH SYSTEMS.

Diopters.	Inches.	Diopters.	Inches.	Diopters.	Inches.	Diopters.	Inches.
0.25	160	2.25	18	5.50	7.0	13	3.0
0.50	80	2.50	16	6.00	6.5	14	2.8
0.75	50	2.75	14	7.00	5.25	15	2.6
1.00	40	3.00	13	8.00	5.0	16	2.4
1.25	32	3.50	11	9.00	4.5		
1.50	26	4.00	10	10.00	4.0	18	2.2
1.75	22	4.50	9	11.00	3.5		
2.00	20	5.00	8	12.00	3.3	20	2.0

The Trial Case (Fig. 262) is a box containing + and — spherical, and + and — cylindrical lenses, arranged in pairs. The spherical lenses (Fig. 260) usually correspond to those given in the preceding table (30 pairs), the weaker ones separated by intervals of 0.25 D., those of moderate strength by

FIG. 262.—The Trial Case of Lenses.

0.50 D., and the stronger ones by 1 D. The cylindrical lenses (Fig. 261) usually run from 0.25 D. to 6.00 D. The + lenses are mounted in nickelled rims, the — lenses in brass rims. Besides these lenses, a complete trial case contains a set of prisms, various metal discs one of which (obturator) is solid and is used to exclude one eye in the examination, and a trial spectacle frame (Fig. 272).

Recognition of the Kind of Lens and Estimation of its Strength.—By moving a *spherical lens* before the eye and looking at an object, the latter will appear to move, rapidly

if the lens is a strong one, slowly if a weak one. If the object seems to move in the *opposite* direction and appears *enlarged*, the lens is *convex*. If the object appears to move in the *same* direction and seems *smaller*, the lens is *concave*.

When a *cylinder* is moved before the eye in the direction of its axis, an object looked at does not appear to change its position; when moved in the opposite direction, objects appear to move as with spherical lenses—in the opposite direction when the cylinder is convex, in the same direction when concave.

Having recognized the character of the lens, the *strength* can be determined by *neutralizing*. Lenses of opposite kind and known strength are taken from the trial case and placed in front of the one to be tested, and the two lenses moved in front of the eye. The neutralizing lens is the one which *stops all apparent movement* of an object looked at, when the combined lenses are moved in front of the eye. The Geneva Lens Measure (Fig. 263) furnishes a very quick and reliable method of determining the character and strength of any lens.

FIG. 263.—Geneva Lens Measure.

Finding the Centre of the Lens.—Unless especially desired (for prismatic effect) the optical centre of the lens should coincide with the geometric centre. To find the optical centre we look at two lines at right angles to each other through the lens held a few inches above. The portion of the vertical and of the horizontal line seen

through the lens is made continuous with the portion seen beyond the lens; then the two lines should cross at the geometrical centre of the lens.

Varieties of Lenses Used to Correct Errors of Refraction :

1. Simple spherical lens, convex or concave.
2. Simple cylindrical lens, convex or concave.
3. Sphero-cylinder, a combination of a spherical with a cylindrical lens.
4. Cross-cylinder, a combination of two cylindrical lenses with their axes at right angles to each other (infrequently used).
5. Simple prism.
6. Prism combined with various lenses.

CHAPTER XXII.

OPTICAL CONSIDERATION OF THE EYE.

THE eye may be considered as an optical instrument, often compared to the photographic camera, in which by means of a refracting (dioptric) system a *small and inverted image* of external objects is formed *on the retina*. The impression received by the rods and cones is conveyed through the optic nerve to the visual cortical area where the visual act is completed and results in the sense of sight.

The eye is well adapted for its function of refraction. It is spherical in shape, about 24 mm. in diameter, and protected externally by the opaque sclera behind and the transparent cornea in front. The outermost portion of the retina consists of a layer of pigment cells which absorbs the excess of light and prevents dazzling.

Dioptric Apparatus of the Eye.—In passing through the eyeball, rays of light traverse the cornea, aqueous humor, lens, and vitreous. The *refracting surfaces* of the eye are the cornea, the anterior surface and the posterior surface of the lens; the *refracting media* are the aqueous humor, the substance of the lens, and the vitreous. These surfaces and media constitute the *dioptric or refractive apparatus of the eye*, a system which is represented by a convex lens of 23 mm. focus; hence in an emmetropic eye in a condition of rest, parallel rays are brought to a focus on the retina. The greatest deflection of rays takes place at the anterior surface of the cornea; additional deviations occur at the anterior and posterior surfaces of the lens. In each case the effect is one of *convergence*. By the term *refraction of the eye*, we mean the changes which the transparent ocular media exert upon rays of light when the eye is in a *state of rest*.

Cardinal Points of the Eye.—It is necessary to be acquainted with the cardinal points of the eye (Fig. 264) in order to

understand the course of rays of light through this organ; they are the two principal points, the two nodal points, and the two principal foci, all situated on the optical axis.

The Principal Points (P, Fig. 264) are two points so related that when an incident ray passes through the first principal point, the corresponding emergent ray passes through the second principal point. These two points are placed so close together in the anterior chamber that they may be considered as one point, situated about 2 mm. behind the cornea.

The Nodal Points (N, Fig. 264) correspond practically to the optical centre of the dioptric system; they are so close together that they may be considered as one point situated near the posterior pole of the lens about 7 mm. behind the cornea.

Rays passing through this point are not refracted and form either the axial or secondary rays.

The First Principal Focus (A, Fig. 264) is that point on the axis at which parallel rays in the vitreous meet; it is situated about 14 mm. in front of the cornea.

The Second Principal Focus (F, Fig. 264) is that point on the axis at which parallel rays meet after being refracted by the dioptric system of the eye; it is situated to the inner side of the macula, between it and the optic disc, about 23 mm. behind the cornea.

The Centre of Rotation of the eyeball (R, Fig. 264) is situated in the vitreous, about 10 mm. in front of the retina.

The Optical Axis (A F, Fig. 264) is the line connecting the centre of the cornea, the nodal point, and the posterior principal focus on the retina.

The Visual Line (O M, Fig. 264) is the line passing from the object looked at, through the nodal point, to the macula.

The Line of Fixation is the line joining the object looked

FIG. 264.—Cardinal Points of the Eye.

at with the centre of rotation; practically it corresponds to the visual line.

The Angle Gamma (γ , Fig. 264) is the angle formed by the optical axis with the line of fixation (practically with the visual line); it varies with the refraction of the eye, being about 5° in emmetropia, larger in hyperopia, and smaller in myopia.

The Angle Alpha is the angle formed by the visual line with the major axis of the corneal ellipse.

REFRACTION OF THE EYE.

Emmetropia.—When parallel rays are focussed exactly on the retina with the eye in a condition of rest, the refraction of the eye is normal or *emmetropic* (Fig. 265) and the condition is known as emmetropia.

FIG. 265.—Emmetropia.

FIG. 266.—Hyperopia.

FIG. 267.—Myopia.

Ametropia.—When, with the eye in a condition of rest, parallel rays are *not focussed on the retina*, but behind or in front of it, the eye is *ametropic*, and the condition is known as ametropia. The forms of ametropia (*errors of refraction*) are hyperopia, myopia, and astigmatism.

Hyperopia is that form of ametropia in which the axis of the eyeball is too short or the refractive power of the eye too weak, so that *parallel rays are brought to a focus behind the retina* (Fig. 266).

Myopia is that form of ametropia in which the axis of the eyeball is too long or the refractive power too strong, so that *parallel rays are focussed in front of the retina* (Fig. 267).

Astigmatism is that form of ametropia in which the *refraction of the several meridians* of the eyeball is *different* (Figs. 293–297).

The Acuteness of Vision and the method of its determination for distance and near have been described with the functional examination of the eye in Chapter II.

ACCOMMODATION.

Accommodation is the *power of altering the focus of the eye* so that divergent rays (those coming from an object nearer than 20 feet) are brought together on the retina; this is accomplished by means of an *increase in the convexity of the lens* and thus in its refractive power. The degree of accommodation must *vary for every distance* of the object; the eye cannot be adapted for two different distances at the same time.

In the emmetropic eye *at rest*, *parallel rays* are brought to

FIG. 268.—The Emmetropic Eye in a State of Rest.

FIG. 269.—The Emmetropic Eye During Accommodation.

a focus on the *retina* (PF , Fig. 268), but rays coming from a near object (*divergent rays*) are focussed *behind* the retina (DX , Fig. 268); hence distant objects appear distinct and near objects blurred. If the refractive power of the eye is increased by *accommodation*, *parallel rays* will be brought to a focus in *front* of the *retina* (PF , Fig. 269), while *divergent rays* will be focussed *on the retina* (DX , Fig. 269); consequently near objects appear distinct and distant objects appear blurred during accommodation.

Mechanism of Accommodation.—The *lens* is an elastic structure, and when released from the flattening influence of its suspensory ligament tends to assume a spherical shape. During accommodation, the *ciliary muscle* (especially the circular fibres) *contracts*; drawing forward the choroid and *relaxing the suspensory ligament*; this diminishes the tension of the lens

capsule and allows the inherent elasticity of the lens to *increase its convexity*. The change in curvature affects chiefly the anterior surface of the lens (Fig. 270). This is *Helmholtz's theory* and the one usually accepted.

FIG. 270.—Section of the Anterior Portion of the Eyeball. The dotted lines illustrate the changes during accommodation.

Lately Tscherning has advanced a different theory: He maintains that the ciliary muscle increases the tension of the suspensory ligament during contraction, and that this causes peripheral flattening of the lens with bulging anteriorly at its centre.

The act of accommodation is *accompanied by contraction of the pupil* and by *convergence* of the visual lines.

The Far Point.—When the eye is in a state of rest, with accommodation completely relaxed, it is adapted for its far point (*punctum remotum*). This is the *farthest point of distinct vision*, and in the emmetropic eye it is situated at *infinity*.

The Near Point (*punctum proximum*) is the *nearest point at which the eye can see distinctly* when employing its maximum amount of accommodation. It *varies* with the amount of accommodation possessed by the eye. The usual plan of determining the near point is to note the shortest distance at which the patient can read the smallest test type (Jaeger, No. 1, Fig. 17) with each eye separately.

The Range of Accommodation is the *distance* between the far point and the near point.

The Amplitude of Accommodation is the *difference* between the refractive power of the eye when *at rest* and when the *accommodation is exerted* to the utmost. It is *expressed in diopters* representing that convex lens which it would be necessary to place before the eye to take the place of accommodation for the near point.

The amplitude of accommodation in diopters is found by dividing 40 by the distance of the near point in inches, or 100 by the near point in centimetres; for example, if the near point of an emmetropic eye is 8 inches or 20 cm., $\frac{40}{8}$ or $\frac{100}{20} = 5$

D. = amplitude of accommodation; this rule applies to *emmetropia*.

In *hyperopia* some of the accommodation is required for distant vision; hence we find the apparent amplitude of accommodation and then add that lens which enables the patient to see distant objects without his accommodation; for example, if the near point of a hyperopic eye is 8 inches or 20 cm., and the patient is compelled to use 2 D. of accommodation for distant objects, his amplitude of accommodation would be $\frac{40}{8}$ (or $\frac{100}{20}$) = 5 + 2 = 7 D. With the same amplitude of accommodation the near point is farther away than in emmetropia, since some of the power of accommodation is expended in adapting the eye for distant objects; and if the near point were the same, the amplitude of accommodation would be greater in hyperopia than in emmetropia.

In *myopia*, since a concave lens is necessary to enable the patient to see distant objects clearly, we must deduct the strength of this glass from that the focal length of which equals the distance of the near point from the eye; for example, if the myopia equals 2 D. and the near point is 4 inches or 10 cm., the amplitude of accommodation will be $\frac{40}{4}$ or $\frac{100}{10}$ = 10 D. — 2 D. = 8 D. With the same amplitude of accommodation, the near point is closer to the eye in myopia than in emmetropia; and if the near point were the same, the amplitude of accommodation would be less in myopia than in emmetropia.

The power of accommodation gradually diminishes and the near point recedes as age advances, owing chiefly to loss of elasticity of the lens. In the emmetrope at 10 years, the p. p. is at 7 cm.; at 40 years it has receded to 22 cm.; at 60 years to 100 cm.; and at 75 years to infinity, the accommodation being suspended and the p. p. coinciding with the p. r. The following table gives the amplitude of accommodation and the near point at various periods of life. The near point applies only to emmetropic eyes, but the amplitude of accommodation applies to all eyes, whether emmetropic or ametropic. There is a tendency toward increased amplitude of accommodation in hyperopia and diminished amplitude in uncorrected myopia.

Year.	Amplitude of Accommodation in Diopters.	Near Point in Centimetres.	Near Point in Inches.	Year.	Amplitude of Accommodation in Diopters.	Near Point in Centimetres.	Near Point in Inches.
10	14.0	7.0	2.8	45	3.5	28.0	11
15	12.0	8.5	3.3	50	2.5	40.0	16
20	10.0	10.0	4.0	55	1.75	55.0	22
25	8.5	12.0	4.7	60	1.0	100	40
30	7.0	14.0	5.6	65	0.75	133	53
35	5.5	18.0	7.0	70	0.25	400	160
40	4.5	22.0	9.0	75	0.0	∞	∞

Presbyopia.—When the near point of the emmetropic eye has receded to a distance at which the finer kinds of work become difficult, the condition is known as presbyopia (Chapter XXIV). This state is the result of a *physiological process* which affects *every eye* and must not be considered a disease.

It is usually said to be present when the near point recedes to a distance of more than 22 cm. (9 inches) from the eye, an event which generally happens *between the fortieth and the forty-fifth years*.

The Association Between Accommodation and Convergence.

—The preceding considerations of the subject of accommodation referred to monocular vision or sight with one eye. With

FIG. 271.—Diagram Illustrating the Unit of Convergence, the Metre Angle.

binocular vision it is necessary to consider *convergence* as well as accommodation, for these two actions (together with the contraction of the pupil) are normally *associated*.

Convergence is the power of directing the visual lines of the two eyes to a near point, and results from the action of the internal recti muscles. When we look at a distant object accommodation is at rest and the visual lines are parallel. When we look at a near object, we are compelled both to accommodate and to converge for that distance; *with a certain*

amount of accommodation, a corresponding effort of convergence of the visual lines is associated.

The *angle* which the visual line makes in turning from a distant object to a near one is called the *angle of convergence*. The unit of convergence is the *metre angle* (M.A.) which is the angle formed by the visual line with the median line at a distance of 1 metre (Fig. 271). If the eyes look at an object half a metre distant the convergence is twice that of the unit, and convergence (C.) = 2 M.A.; if directed toward a point one-third of a metre distant, C. = 3 M.A.; if toward an object 2 metres distant, C. = $\frac{1}{2}$ M.A.

The *emmetropic* eye requires for each distance of binocular vision as many *metre angles* of convergence as it needs *diopters of accommodation*. To see an object at 1 metre distance, 1 metre angle of convergence is required and also 1 diopter of accommodation; at 10 cm., 10 metre angles of convergence and 10 D. of accommodation would be required.

This harmonious relationship between accommodation and convergence is not, however, unchangeable. Within certain limits either of these actions may take place independently of the other.

The Range or Amplitude of Convergence.—The *far point of convergence* is the point to which the visual lines are directed when convergence is at rest; the *near point of convergence* is the point to which the visual lines are directed with the maximum amount of convergence. The distance between the far point and the near point of convergence is the *amplitude of convergence*; it is expressed by the greatest number of metre angles of convergence of which the eyes are capable. In a state of rest the far point of convergence is at infinity and the visual lines are either parallel or more commonly somewhat divergent, in which case convergence is spoken of as *negative*. In cases of convergent squint, the visual lines deviate inward even when convergence is relaxed; convergence is then said to be *positive*. In a case of divergent squint convergence is a negative quantity. Normally, the eyes diverge during sleep.

Methods of Determining the State of Refraction of the Eye.—There are three principal methods of testing the refraction of the eye: (1) the *subjective method*, in which the refraction is estimated by the acuteness of vision with test types and trial lenses; (2) the *ophthalmoscope*; and (3) *retinoscopy*; the last two are objective methods.

Every examination should be undertaken in a systematic manner. We begin with the *external examination* of the eyes as described in Chapter I. Next the patient is taken into the *dark room* and the *media and fundus* are examined with oblique illumination and the ophthalmoscope (Chapter III.). Then the state of the *refraction* is determined with the *ophthalmoscope*. The retinoscopic mirror is now employed to estimate the state of the refraction with the *shadow test*; and the *ophthalmometer* may also be brought into service. Finally, the patient is examined by the *subjective method* with test lenses and test types. By employing this order we will save time, since the ophthalmoscopic examination may show changes in the media or fundus which convince us of the impossibility of improving the patient's vision with glasses, or lead us to be satisfied with a limited result. The *objective methods* of determining the state of refraction of the eye give very close and accurate results; the *subjective method* serves to verify these conclusions and often perfects them.

THE DETERMINATION OF THE STATE OF REFRACTION BY TEST TYPES AND LENSES (THE SUBJECTIVE METHOD).

After having determined the acuteness of vision for distance as described on p. 10, we endeavor to ascertain *which lenses* are necessary to correct any error of refraction and to *bring the vision up to the normal* $\frac{20}{20}$. The patient is placed in front of the test types, which must be well illuminated by daylight or artificial light, at a distance of 20 feet. The trial frame (Fig. 272) is worn by the patient, and the left eye excluded by means of a solid metal disc. After testing the right eye, we proceed with the left.

If the patient reads $\frac{20}{20}$, we may assume the absence of myopia

and of astigmatism; the patient is either *emmetropic* or has *hyperopia*. A weak convex spherical lens (+0.50 D. Sph.) is held in front of the eye; if he is still able to read the $\frac{2}{20}$ line as well as without a lens, he has hyperopia, and the *strongest* convex spherical lens with which he can read $\frac{2}{20}$ is the measure of his manifest hyperopia. Even though he accepts a convex spherical lens, this is probably not the measure of his total hyperopia, which can be estimated in young persons only after the eye has been placed under the effects of a cycloplegic.

FIG. 272.—The Trial Frame.

The difference between the manifest and the total hyperopia is known as the latent hyperopia; it is this portion which is discovered after accommodation has been paralyzed.

If the patient reads $\frac{2}{20}$, and a weak convex spherical lens blurs his vision, he is either *emmetropic* or has *hyperopia* which is *latent*.

If the patient's vision is below normal, and instead of reading $\frac{2}{20}$ he reads $\frac{2}{40}$ or $\frac{2}{70}$, he either has considerable manifest *hyperopia*, or else he is *myopic* or *astigmatic*; or he may have a combination of these errors. If hyperopic, spherical lenses will improve his vision. If such improvement does not result upon placing convex spherical lenses before the eye, we may try a weak concave spherical lens; if this aids his vision, he is myopic, and the *weakest* concave spherical lens that brings his vision to $\frac{2}{20}$ is the measure of his myopia. If concave spherical lenses do not improve the vision, we assume the existence of astigmatism; and cylinders, alone or in combination with spherical lenses, are placed in front of the eye for the purpose of estimating the kind, the axis, and the amount of astigmatism.

This is, briefly, the method pursued in determining the state of refraction by means of the acuteness of vision (*subjectively*); greater details will be supplied in discussing the errors of refraction. But, as already pointed out, it is better and saves time to precede this subjective test by the objective methods, using the former to confirm the findings of the others; this is especially advisable if the error of refraction be a difficult or complicated one.

The Vision for Near is also tested. A page of *Jaeger's test types* (Fig. 17) is given to the patient, and we note the *smallest* type which he is able to read with *each eye separately*, the *distance* which he selects, and the *nearest* and *farthest* distances at which he is able to read. These data give us valuable information regarding the state of refraction. In myopia, the patient will hold the print at a closer distance than normal. In presbyopia he will hold it at a greater distance than normal.

THE OPHTHALMOSCOPE AS A MEANS OF DETECTING AND ESTIMATING REFRACTIVE ERRORS.

The Ophthalmoscope at a Distance gives us *qualitative information* regarding errors of refraction. When the patient is *emmetropic*, no details of the fundus will be seen when the light is thrown into the eye from an ophthalmoscope held at a distance of 15 inches. If some part of the disc or vessels is seen, the patient is *ametropic*. If the examiner moves his head from side to side and the *vessels* seem to move in the *same* direction, the case is one of *hyperopia* (for in hyperopia the rays emerge divergent and the image is a virtual, erect one). If the *vessels* seem to move in the *opposite* direction, the case is one of *myopia* (since in myopia the emerging rays are convergent and form an inverted image). If the *vessels of one meridian only* are seen, *astigmatism* is present; this is hyperopic if the vessels move with the movements of the observer's head, myopic if they move in the opposite direction, and mixed, if one set move with and the other against them.

The Indirect Method is not used for determining the amount of error of refraction, but we obtain *information of the form*

of *ametropia* by noting the size and shape of the inverted image of the disc and its behavior upon withdrawing or approaching the lens before the patient's eye. If no change takes place in the shape and size of the image when we withdraw the lens, the eye is *emmetropic*. If the shape remains the same but the image becomes smaller when the lens is withdrawn, it indicates *hyperopia*. If the shape remains the same but the image becomes larger on withdrawing the lens, the case is one of *myopia*. In *astigmatism* the disc usually appears oval and the shape of its image changes in withdrawing the lens; one diameter decreases or increases while the other remains stationary in simple astigmatism; both increase or decrease unequally in compound astigmatism; and one increases and the other decreases in mixed astigmatism.

The Direct Method is a very valuable means of determining the condition of refraction, and, in case of error, the kind and the amount; reliable findings are obtained, however, only after considerable practice. For accurate results, it is *necessary* that the *accommodation* of both patient and observer be *in abeyance*. The beginner always has difficulty in relaxing his accommodation, and requires considerable training before he masters this necessary step (p. 27). The patient's accommodation is suspended by directing him to look at the wall or at a distant object, or, better, by the use of a cycloplegic. The examiner, if ametropic, corrects his error by wearing suitable glasses, by having a special correcting lens applied to the sight-hole of the ophthalmoscope, or by subtracting the amount of his error from the result which he obtains in the examination. The examination is conducted in the manner described on p. 25; for accurate results it is essential that the *shortest possible distance* separate the eye of the patient from that of the observer.

Emmetropia.—The examiner selects a *blood-vessel* at the outer margin of the disc or between the disc and the macula. If the vessel appears *distinct*, and if upon rotating a $+0.50$ D. lens before the sight-hole it becomes blurred, the eye is *emmetropic*. Rays coming from an emmetropic eye at rest are

parallel, and the observing eye will focus these rays on the retina (Fig. 273).

Hyperopia.—If the image is *blurred*, we rotate the lens disc of the ophthalmoscope so as to place *convex lenses* in the sight-hole; if these render the image distinct the eye is *hyper-*

FIG. 273.—The Estimation of the Refraction by the Direct Method of Ophthalmoscopy. Both patient and observer are emmetropic.

opic. The *strongest convex lens* with which we get a distinct image is the measure of the hyperopia. In Fig. 274, *H* is the hyperopic eye under examination, and *E* the emmetropic eye of the observer. Rays from *a* emerge divergent as though

FIG. 274.—The Estimation of Hyperopia by the Direct Method of Ophthalmoscopy.

coming from *x*. The convex lens $+L$ makes them parallel so that they focus at *b*, on the retina of *E*, the emmetropic eye of the observer.

Myopia.—If when the image appears *blurred*, a convex lens makes it more indistinct, we rotate the disc of the ophthalmoscope so that *concave lenses* are brought opposite the sight-hole. If these render the image *distinct*, the eye is myopic. The *weakest concave lens* is the measure of the myopia. We stop at the weakest concave lens which accomplishes this, since stronger lenses of this sort would only encourage the observer

to accommodate. In Fig. 275, *M* is the myopic eye under examination, and *E* the emmetropic eye of the observer. Rays from *a* leave the myopic eye convergent and would meet

FIG. 275.—The Estimation of Myopia by the Direct Method of Ophthalmoscopy.

at *X*. The concave lens — *L* renders them parallel so that they are focussed at *b*, on the retina of the observer.

Astigmatism.—We find the lens with which a small *vertical vessel* is seen distinctly, and then the lens which enables a small vessel *at right angles* to be seen clearly, always remembering that the lens which clears up the image of a vessel in one direction is the measure of the refractive error of the meridian at right angles to it.

Suppose the horizontal vessels appear distinct without any lens—then the vertical meridian is emmetropic; and that the vertical vessels require a convex or a concave lens to render them distinct—then the horizontal meridian is hyperopic or myopic; the case is one of *simple* hyperopic or myopic *astigmatism* (Figs. 293 and 294).

If both vertical and horizontal vessels are rendered distinct by convex lenses but a stronger one can be used for the horizontal, the case is one of *compound hyperopic astigmatism* (Fig. 295) with the vertical meridian the more hypermetropic; if both vertical and horizontal vessels are best seen with concave lenses but of different strength, the case is one of *compound myopic astigmatism* (Fig. 296).

If the vertical vessels can be seen clearly with a convex lens and the horizontal vessels require a concave lens, the case is one of *mixed astigmatism* (Fig. 297), the horizontal meridian being hyperopic, the vertical meridian myopic.

RETINOSCOPY.

Retinoscopy (*The Shadow Test, Skiascopy*) is a very accurate, objective method of determining the state of the refraction by illuminating the eye with a plane or concave mirror, and observing the *direction of the movement* of the retinal illumination and its bordering shadows, when the mirror is rotated. The shadow test has many *advantages*: It can be used in *children, illiterates*, and in *markedly defective sight*; it is entirely *objective*, and hence requires no co-operation on the part of the patient; it is *quick* and *accurate*; and it requires no expensive apparatus.

The Principle of Retinoscopy is the finding of the *point of reversal or the myopic far point*. In myopia an inverted image is formed in the air in front of the eye at the far point—the distance from which rays would be focussed on the retina; this point is known as the point of reversal. If the eye is hyperopic or emmetropic, a convex lens is placed before it so as to give it an *artificial far point*.

When light is thrown into the eye by means of a plane or concave mirror at a distance of one metre, the fundus is illuminated. By looking through the sight-hole of the mirror an

FIG. 276.—Retinoscopic Mirror.

FIG. 277.—Small Retinoscopic Mirror upon Metal Disc.

observer will see the *illuminated portion* (red fundus reflex) and also the *shadow* bounding this bright area. On *rotating the mirror* the illuminated area and the shadow will *move across the pupil*.

The examination is conducted in the *dark room*, the darker the better. The *source of illumination* is placed *above the head of the patient* and somewhat behind so that his face is in darkness (Fig. 278, *A*). An *Argand burner* is the most common form of illumination; it is often surrounded by an asbestos chimney with a large circular opening opposite the brightest part of the flame, so that the light is thrown only toward the observer. Some oculists prefer the light placed near the observer, about 6 inches to his left and in front, with a small (10 mm.) opening in the opaque chimney (Fig. 278, *B*).

Either a plane or a concave mirror may be employed; the *plane mirror* has certain advantages and is more commonly used. The retinoscopic mirror (Fig. 276) usually has a diameter of 3.5 cm. with a 3 mm. opening, though sometimes a 2

FIG. 278.—The Retinoscopic Examination.

cm. mirror upon a 4 cm. metal disc (Fig. 277), with a 2 mm. opening, is preferred by those who place the light near the observer.

The patient is seated, his *pupils* are *dilated*, and preferably his *accommodation* should be *paralyzed*. He is directed to *look at the forehead of the examiner*. Each eye is tested *separately*, and one eye is usually covered.

The observer is seated at *one metre distance* (Fig. 278); he should *wear correcting lenses* if ametropic; he need not relax his accommodation as in using the ophthalmoscope, since this does not influence the result.

If now the mirror be rotated slowly from side to side on its vertical axis so that the light moves across the pupil horizontally, the observer will see an *illuminated area* and a *shadow* coming from behind the pupil; if the mirror be rotated on its horizontal axis the light will move across the pupil vertically. *The direction of movement of this light and shadow as compared to that of the mirror depends upon the state of the refraction of the eye.* The shadow moves either in the same (with) or the opposite direction (against) to that of the mirror; if we turn the mirror toward the right and the shadow moves toward the right, we say it moves with the mirror; if upon turning

FIG. 279.—Retinoscopic Illumination and Shadow in Astigmatism.

FIG. 280.—Retinoscopic Illumination and Shadow in Myopia, Hyperopia, or Emmetropia.

the mirror toward the right the shadow moves toward the left, we say it moves against the mirror.

With the plane mirror, the shadow moves with the mirror in hyperopia, emmetropia, and in myopia of less than 1 D., and against the mirror, in myopia of more than 1 D.

The illuminated area and the shadow appear to move with the mirror when the observer is within the point of reversal, and against the mirror when he is beyond this point.

Besides the direction of the movement, we acquire information from the *brightness*, the *form*, and the *rate of movement* of the light and shadow: If the reflex is bright, its edge sharp, and the light and shadow move rapidly, the error of refraction is a low one; if the illumination is dull, its edge indistinct, and the movement of light and shadow slow, the error is a high one. If the shadow has a *straight edge* it is an indication of *astigmatism* (Fig. 279); in hyperopia, myopia, or emmetropia, the shadow has a *crescentic edge* (Fig. 280).

Next we *find the correcting lens*—i.e., the lens which causes a *reversal* of the direction of movement of the shadow. This lens will be correct for the distance separating the observer from the patient, one metre. For infinity, we must *add* -1 D. to all results; this increases the myopia 1 D., and diminishes hyperopia 1 D.

If with the plane retinoscope the *shadow moves against* the mirror, we place *concave* spherical lenses before the eye until we succeed in causing a reversal of the movement of the shadow—i.e., cause it to move with the mirror; this lens, to which we add -1 D., is the measure of the patient's *myopia*. Suppose on placing -1 D. before the eye, the shadow still moves against the mirror, the same with -2 D., but with -2.50 D. the movement of the shadow is reversed; then $-2.50 + -1. = -3.50$ D. is the correction.

If with the plane retinoscope, the *shadow moves with* the mirror, the eye may be hyperopic, emmetropic, or myopic less than 1 D. In such a case we begin by adding a convex lens of $+0.50$ D. If this causes a reversal of the shadow the eye is *myopic* 0.50 D., since $+0.50 \subset -1.00 = -0.50$ D.

If the $+0.50$ D. lens does not alter the direction of the movement of the shadow, but the next lens ($+1$ D.) causes a reversal, the eye is *emmetropic*, since $+1.00 \subset -1.00 = 0 = E$.

If the $+1.00$ D. lens has no effect upon the direction of movement of the shadow, the eye is *hyperopic*; we place stronger $+$ spherical lenses before the eye until we find the one which causes a reversal of the movement of the shadow. Say this is $+4$ D.; then the hyperopia amounts to $+4.00 \subset -1.00 = +3$ D.

In the previous examples, the results were the same whether the mirror was rotated upon its vertical or its horizontal axis. In *astigmatism*, upon correcting each of the two principal meridians separately, one meridian will require a different lens to cause a reversal of the shadow than the other. The most common positions of the two meridians in astigmatism are *vertical* and *horizontal*. But frequently the edges of the shadows lie more or less *obliquely*. In such cases the mirror

must be rotated so that the light moves obliquely and parallel with the movement of the shadow.

For example, suppose the shadow moves with the mirror in both meridians, but one shadow is more distinct and moves more quickly than the other; we diagnose astigmatism. Then we correct the vertical meridian and find it requires $+ 2$ D. for the reversal of the shadow. Next we find that in the horizontal meridian $+ 4$ D. is required for reversal. We add $- 1$ D. to each of these results and have $+ 1$ D. vertical and $+ 3$ D. horizontal. The case is one of compound hyperopic astigmatism and requires for its correction $+ 1$ D. spherical lens combined with $+ 2$ D. cylinder, axis vertical.

CHAPTER XXIII.

ERRORS OF REFRACTION.

IN *emmetropia* (E.) the eye in a state of rest, without accommodation, focusses the image of distant objects exactly upon the retina (Fig. 265); such an eye enjoys distinct vision for distant objects without effort or fatigue. Any variation from this standard constitutes *ametropia*, a condition in which the eye, in a state of rest, is unable to focus the image of distant objects (parallel rays) upon the retina. *Ametropia* includes *hyperopia*, *myopia*, and *astigmatism*. The effects of *ametropia* are not only *indistinctness* of vision but various pains and other symptoms comprised under the term *asthenopia* (weak sight, eye strain).

HYPEROPIA.

Hyperopia (*Hypermetropia*, *Farsightedness*, H.) is an error of refraction in which, with accommodation completely relaxed, *parallel rays* (rays from distant objects) are brought to a *focus behind the retina* (Figs. 266, 281); divergent rays (from near objects) are focussed still farther back.

Etiology.—It is most commonly due to *shortening of the antero-posterior diameter* of the eyeball (*axial H.*), less frequently to diminished convexity of the refracting surfaces of the eye (*H. of curvature*), changes in the media, or absence of the lens (*aphakia*). It is by far the *most frequent error* of refraction and is *congenital*; in a certain sense it may be considered due to imperfect development of the eye. It is often *hereditary*. Children are usually *hyperopic at birth* and subsequently become less hyperopic, emmetropic, or even myopic.

The Course of Rays.—The hyperopic eye cannot, without accommodation, see either distant or near objects distinctly (Fig. 281). In a condition of rest, it is adapted for conver-

gent rays and these are not found in nature. To focus *parallel rays* on the retina it must either *accommodate*, *i.e.*, increase the convexity of its lens as shown in Fig. 282, or a *convex lens* of such a strength that the rays are made sufficiently convergent to be brought to a focus on the retina (Fig. 283) must be placed in front of the eye.

FIG. 281.—Hyperopic Eye in a State of Rest.

FIG. 282.—Hyperopic Eye during Accommodation.

FIG. 283.—Hyperopia Corrected by a Convex Lens.

FIG. 284.—Emmetropic Eye Accommodating for Near Vision.

FIG. 285.—Hyperopic Eye Accommodating for Near Vision.

To focus *divergent rays*, *i.e.*, rays from near objects, the hyperope must not only *accommodate* the amount required of an emmetropic eye (Fig. 284), but an *additional amount* to compensate for his error. In other words, he requires some accommodation constantly in order to see distant objects distinctly, and in addition the amount equal to that required by the emmetrope for near vision (Fig. 285). Such an eye (when the error is uncorrected) is *never in a condition of rest* as long as it enjoys distinct vision.

Changes in the Eye.—As a result of the constant strain and overaction of the *ciliary muscle*, the latter becomes *hypertrophied*, especially its circular fibres (Fig. 287); it remains in a greater or lesser condition of spasm. In high degrees of H.

the eyeball may be diminished in size, the anterior chamber shallow, the sclera flat with a sharp curve at the equator, and there may be an apparent external squint, owing to the high angle gamma (see p. 270).

Varieties.—Hyperopia is divided into (1) manifest, (2) latent, and (3) total.

(1) *The manifest hyperopia* (Hm.) is that which is detected *without paralyzing the accommodation* and is represented by the strongest convex glass with which the patient sees most distinctly; it corresponds to the amount of accommodation which he relaxes when a convex lens is placed before the eye. Manifest hyperopia may be either *facultative*, when it can be overcome by an effort of accommodation, or *absolute*, when it cannot be overcome in this manner.

(2) *The total hyperopia* (Ht.) is the *entire amount* of hyperopia detected after the *accommodation* has been *paralyzed* or during complete relaxation of the ciliary muscle.

(3) *The latent hyperopia* (Hl.) is the difference between the Hm. and the Ht., and is the amount which is *habitually concealed* and is discovered only after the use of a cycloplegic.

The application of these terms can be illustrated by considering an example of H. of 2.5 D. in a young person. If in such a case $V = \frac{20}{40}$, and, without the use of a cycloplegic, a + 1 D. spherical lens brings up the vision to $\frac{20}{20}$, we say Hm. = 1 D.; if now we paralyze the accommodation with a cycloplegic and find $V = \frac{20}{100}$, and that a + 2.50 D. spherical lens increases this to $\frac{20}{20}$, the Ht. = 2.50 D.; the difference between 2.50 D. and 1.00 D. = 1.50 D. = Hl.

The *ratio* between the manifest and the latent hyperopia is *not constant*; it depends more or less upon the *age* and *vigor* of the individual. In *youth*, the amount of Hl. is apt to be considerable, and consequently a cycloplegic is essential in

FIG. 286.

FIG. 287.

FIG. 288.

FIG. 286.—Section of the Ciliary Muscle in an Emmetropic Eye.

FIG. 287.—Section of the Ciliary Muscle in a Hyperopic Eye.

FIG. 288.—Section of the Ciliary Muscle in a Myopic Eye.

estimating the amount of hyperopia. The *older* a person grows, the less accommodative effort he is able to make; hence the Hl. becomes less, and the Hm. greater. In *old* persons there is no Hl., the total hyperopia becoming manifest.

Symptoms.—Unless the error be considerable or the patient be advanced in years, there is usually *good vision for distance*. A great many patients with hyperopia present *no symptoms* whatever; this is apt to be the case when the hyperope is young, in good health, and indulges in plenty of outdoor exercise. Under these circumstances he is apt to accommodate for his optical defect without any evidence of overaction of the ciliary muscle. In other cases, the accommodative efforts will be unequal to the task imposed in near work, and as a result the hyperopia will give rise to *accommodative asthenopia* (weak sight, eye strain).

The *Symptoms of Asthenopia* show themselves particularly after reading, writing, sewing, and other forms of *near* application, especially in the *evening* and with *artificial illumination*. They comprise *pain* referred to the eyes or above the eyes; *headaches*, usually frontal, but also occurring in the occiput and other parts of the cranium; various *neuralgias*; *congestion* of the conjunctiva and margins of the lids; *lacrymation*, blinking, and slight photophobia; *burning* sensation in the lids; and *blurring* of near vision. These symptoms are more pronounced whenever the general health is unsatisfactory.

With advancing years, there will be greater difficulty in reading without correcting glasses.

In *early childhood*, hyperopia often causes *convergent squint* in a patient whose fusion sense is deficient (p. 338).

In *children*, H. shows a physiological tendency to *diminish* with the growth of the child; after puberty it may become greater. In the adult it remains stationary; after fifty there is a tendency to a slight increase.

Hyperopic eyes are *predisposed* to conjunctivitis and blepharitis, phlyctenular affections, congestion of the retina and choroid, internal squint, and glaucoma.

Tests.—These have been described in the preceding chapter. They are the following:

The Subjective Test with Test Types and Test Lenses.—We first record the acuteness of vision and then place convex lenses before the eye, commencing with $+0.50$ D. The *strongest lens* with which the patient sees $\frac{2}{20}$ or better is the measure of the *manifest* hyperopia. Then the accommodation is paralyzed and the test repeated; the strongest lens “accepted” (*i.e.*, with which the patient’s vision is improved) is the measure of his *total* hyperopia. Such an examination is recorded as follows:

O. D. V = $\frac{2}{20}$; Hm. 0.50 D.; Hom: V = $\frac{2}{100}$; $\frac{2}{20}$ w. $+2$ D. S. Translated, this line would read: Oculus dexter (right eye), vision equals $\frac{2}{20}$; manifest hyperopia 0.50 D.; after the use of homatropine, vision equals $\frac{2}{100}$, increased to $\frac{2}{20}$ with a convex spherical lens of 2 diopters.

The Ophthalmoscope at a Distance.—The retinal vessels appear to move in the same direction as the observer’s head.

The Ophthalmoscope, Indirect Method.—On withdrawing the lens in front of the patient’s eye, the size of the disc diminishes.

The Ophthalmoscope, Direct Method.—The disc and vessels can be seen distinctly with a convex lens in the sight-hole, the strongest being the measure of the H.

Retinoscopy.—With the plane mirror held at one metre, the shadow moves with the mirror; the direction of movement is reversed by convex lenses placed in front of the patient’s eye. The lens which causes a reversal, minus 1 D., is the measure of the H.

Treatment consists in prescribing such *convex spherical lenses* as will make *vision distinct* and enable the patient to do near work *without fatigue*. The mere existence of hyperopia is no indication for the use of correcting glasses unless these are worn in childhood for the cure of convergent squint. It is only when there is a diminution in the acuteness of vision or when symptoms arise indicating eye strain that convex lenses should be used.

Though theoretically it would seem proper to prescribe the full correction (for Ht.), practically there are many objections and exceptions to this. In *every case* of hyperopia occurring

in *children* and in *young adults*, the *accommodation* should be *paralyzed* and the *total error* estimated so as to serve as a basis for the prescription for glasses.

The *symptoms* of the individual give us reliable indications as to the *proportion of the Ht. which ought to be corrected*, and the *constancy* with which the glasses should be worn. In cases of squint, and when glasses are prescribed for the relief of conjunctivitis, blepharitis, and headaches which are continuous, or the occurrence of which is independent of near use of the eyes, they must be worn constantly. In other cases, glasses should be worn continuously or only for near, according to whether the symptoms are always present or follow only after using the eyes for reading and the like. When distant vision is perfect and comfortable, and the patient does not suffer from any symptoms except when engaged in near work, glasses need be prescribed only for such use; this is often the case in young adults who enjoy good health. Under such circumstances, the correction of the Hm. may be sufficient; or we may add to this the correction for part of the Hl., or we may correct the Ht. In cases in which the correction is only partial, the glasses may require changing from time to time. In hyperopes after forty-five, convex lenses should be worn to improve distant vision, and a stronger pair for near; the weaker set is for the H., the stronger pair to correct both the hyperopia and the presbyopia. Under such circumstances, *bifocal lenses* (Fig. 308) are very convenient, the upper segment corresponding to the weaker glass, the lower to the stronger.

MYOPIA.

Myopia (*Nearsightedness*, *Shortsightedness*, M.) is that refractive condition in which, with accommodation completely relaxed, *parallel rays* are brought to a *focus in front of the retina*. These rays cross in the vitreous; when they reach the retina they have become divergent, forming a circle of diffusion and consequently a blurred image (Fig. 289, *PPF*). Certain divergent rays, coming from the myopic far point, are focussed on the retina (Fig. 289, *DX*) without accommodation.

The greatest distance at which the patient can read fine print is the *far point*. This is always at a definite distance corresponding to the amount of *M.*; the higher the *M.*, the closer to the eye is the far point; the distance of the latter is the *measure of the M.* For example, if the far point is at 20 inches (.5 metre) the $M. = 2 \text{ D. } (\frac{40}{20} \text{ or } \frac{100}{50} = 2)$; if at 10 inches (.25 metre) the $M. = 4 \text{ D.}$ In these two instances concave lenses of 2 and 4 D. respectively would render parallel rays as divergent as if they came from a distance of 20 and 10 inches (.5 and .25 metre); and with these lenses, the myope would be able to see distant objects distinctly (Fig. 290).

Etiology.—Myopia almost always depends upon a *lengthening of the antero-posterior diameter* of the eyeball (*axial myopia*); in *M.* of 3 D., for example, the eyeball measures 24 mm. in its antero-posterior diameter, and in *M.* of 10 D., 27 mm. from before backward, instead of 23 mm., the normal diameter. Much less frequently *M.* is due to increased curvature of the cornea (anterior staphyloma and keratoconus), increase in the refraction of the lens from swelling in incipient cataract (often referred to by the laity as “second sight,” because it sometimes enables an old person again to read print for a time without glasses), and spasm of accommodation. *The determining causes* are associated with the demands which *civilization and education* make upon near vision. It is rarely congenital, though there is often an *hereditary* tendency for its development. It is an *acquired* change which commences at an early age when, during the developing period, the *eyes are used excessively or improperly for near work*. Its occurrence is in direct proportion to the standard of education, and also bears a certain relation to the general health and strength of the individual. It is much more common in cities than in

FIG. 289.—The Focussing of Parallel and Divergent Rays in Myopia.

FIG. 290.—The Correction of Myopia by Means of a Concave Lens.

the country. It increases in percentage from the lower to the higher classes in schools and universities.

Excessive study with insufficient outdoor exercise, fine or *indistinct print*, *poor illumination*, opacities of the cornea and other lesions causing imperfect vision, *faulty* construction of *desks*, *sedentary* habits, and *poor health* are among the frequent exciting causes of myopia, especially in those who are predisposed.

The cause of the lengthening of the eyeball is attributed (1) to pressure of the extraocular muscles during excessive convergence causing the posterior pole, which is the least resistant part of the eyeball, to bulge; (2) to congestion, inflammation, and softening of the layers of the eyeball, together with increased tension, produced by fulness of the veins of the head as a result of stooping postures and other predisposing causes; and (3) to the shape of the orbit in broad faces causing excessive convergence, as seen in the German race, which is especially subject to this error of refraction.

Clinical Forms.—In most instances, myopia is of low degree, develops during youth, and then comes to a standstill or increases very little; this is known as *stationary* or *simple myopia*.

In other cases, the error reaches a considerable height in youth, and *increases* steadily up to the twenty-fifth year or even later, resulting in a *high degree* of myopia; this is known as *progressive myopia*. These are the cases which are accompanied by *destructive changes* in the choroid and other parts of the eye, leading to a considerable impairment of vision, and even blindness, and in which myopia may properly be considered a *disease*. Extreme cases of progressive myopia are known as *malignant myopia*.

Symptoms depend on the degree of myopia.

In *slight degrees* and in many cases of moderate amount, there are often no symptoms except *indistinct vision for distance*. Near work can be accomplished with comfort; in fact, since the myope requires less accommodation than the emmetrope, he may have an advantage in close application. It is on this account that the circular fibres of the ciliary muscle are less developed than in the emmetropic eye (Fig. 288).

In other cases of moderate myopia and in *high degrees*, *distant vision is very indistinct*; there is often *pain* in the eyes after near use; the patient will be unable to continue at work for any length of time on account of excessive convergence; the *eyes tire easily*, are sensitive to light, and *irritable*; there are black spots before the eyes (*muscæ volitantes*), and sometimes bright flashes of light. In some cases there may be absolute scotomata.

In *high myopia*, there are often prominence of the eyes, a deep anterior chamber, and dilated pupils; the patient is apt to screw the eyelids together; there is sometimes an appearance of convergence. The strain of excessive convergence is so great and painful, that the effort is sometimes given up and divergent squint results.

Ophthalmoscopic Signs.—In low (less than 3 D.) or moderate (3 to 6 D.) degrees, there are frequently no changes except a crescent-shaped patch of atrophy of the choroid of whitish or grayish color, embracing the outer side of the disc; this is called a *myopic crescent*.

In *high myopia* (more than 6 D.), a well-marked *crescent* is usually found, often *posterior staphyloma* (bulging of the sclera, Fig. 168, Plate XIV), and there may be patches of *choroidal atrophy* with pigmented margins, exposing the sclera. In *progressive cases*, there are frequently added to these lesions atrophic and pigment changes in the macular region (Fig. 165, Plate XIII), *hemorrhages*, especially at the yellow spot, *fluid vitreous* (causing tremulous iris), *floating bodies* in the vitreous, and opacities of the lens; sometimes there is detachment of the retina. Owing to these changes, the *vision* is often very markedly *reduced* and is sometimes *lost* in severe forms of progressive myopia.

Tests.—*The Subjective Test with Test Types and Test Lenses.* Distant vision is below the normal and the patient requires a *concave spherical lens* to bring the sight up to $\frac{20}{20}$. The *weakest lens* which accomplishes this is the measure of the myopia. In young persons it is important to *paralyze the ciliary muscle*, so that spasm of accommodation will not cause the patient to select too strong a lens. The results are re-

corded as follows: O.D. $V = \frac{20}{200}$; $\frac{20}{20}$ w. — 4 D. Sph. The reduction in distant vision generally corresponds to the amount of M.

The myope is able to read the smallest print, but at a shorter distance than that which the emmetrope selects. The farthest distance at which he is able to read the finest print is his *far point*, and this is also the *measure of his M*.

The Ophthalmoscope at a Distance shows an inverted image of the fundus which appears to move in the opposite direction to the examiner's head.

The Ophthalmoscope, Indirect Method.—The disc appears small and seems to increase in size upon withdrawing the objective lens.

The Ophthalmoscope, Direct Method.—The fundus cannot be distinctly seen until a concave lens is placed behind the mirror; the weakest concave lens with which the details are seen clearly, indicates the amount of myopia.

Retinoscopy.—With the plane mirror and the observer at 1 metre distance, the shadow moves in the opposite direction (except when M. is less than 1 D.), and is reversed by the addition of concave lenses. The lens which causes reversal plus — 1 D. is the measure of the M. In high M. the shadow is very faint, but becomes plainer when concave lenses are added.

Prognosis.—In low and moderate degrees of *stationary myopia*, the prognosis is *good* when suitable glasses are worn. *Progressive myopia* is always a *serious* condition, especially when the choroidal and vitreous changes are marked; it frequently necessitates absolute cessation of all near work. In *malignant myopia* the prognosis is *grave*.

Treatment consists in prescribing suitable glasses, limiting the amount of work so that there will be no fatigue, and preventing the progress of the disease.

In general terms, it is proper to give a *full correction* for low and moderate myopia in young persons, as soon as discovered, and to direct these glasses to be worn for *both distance and near*; this places the eyes under normal conditions of vision and accommodation. The glasses must be prescribed after

the accommodation has been paralyzed, so that there will be no danger of over-correction on account of spasm of accommodation. Full correction corresponds to the *weakest concave spherical lens* which, *with accommodation paralyzed*, gives the best vision. In low degrees of M. an adult may be allowed to read without glasses if he finds this convenient.

In *high myopia*, the full correction is prescribed for distance, and about two-thirds correction for near work; the reading-glasses should be such as to enable the patient to read at a comfortable distance, say 13 inches (33 cm.). Suppose — 10 D. gives the best vision for distance; then — 10 D. + 3 D. Sph. = — 7 D. will enable him to read at this distance without accommodation.

After the age of 45, the distance glasses cannot be worn for near work, since the convex lenses usually required for presbyopia must be added to the concave lenses, thus reducing the strength of the latter.

In prescribing glasses in M. every case must be considered on its merits. Many myopes wear strong lenses, representing the full correction, constantly and with absolute comfort; others require two sets of lenses, one for distance and a weaker pair for reading.

In order to check any tendency to increase of M., *rigid hygienic rules*, both local and general, should be carried out. These are of especial importance in the young. The patient's *habits* should be *regulated* so that he will enjoy good health. He should have an abundance of *outdoor exercise* and plenty of *sleep*.

Near work should be restricted and the patient not be allowed to read too long at a time. The book should be held at 13 inches (33 cm.). In most cases the *full correcting lenses* should be worn for near work. The *illumination* should be good, neither too bright nor too dim, and should come *from behind*; the myope should avoid reading at dusk or with feeble illumination; the amount of work done with artificial light should be limited. The *print* should be large and clear, with ample spacing. *Desks* should be constructed so that the sitting posture is comfortable, and so that the child is not en-

couraged to stoop over his books; the myope must be taught not to bend over his work, but to lift the latter to the required distance from the eyes.

If notwithstanding such precautions, myopia progresses, it is necessary to forbid all near use of the eyes. A good plan is to take the patient from school and send him to the *country* for a long period, during which he is instructed to be out-of-doors as much as possible, and to avoid all reading and near work. Young adults suffering from progressive myopia should *give up sedentary occupations* necessitating close application, and select those in which but little near use of the eyes is required.

Operative Treatment.—In children and young adults with *high myopia*, uncomplicated by excessive pathological changes in the fundus, the *removal of the lens* by discission and subsequent extraction is frequently very successful. The lens is needled, and after several days the swollen lens substance is removed by extraction. The operation is limited to *M. of 15 D. or more*. After the removal of the lens the eye may be almost emmetropic, since the optical effect in such highly myopic eyes is quite different from that which follows extraction of the lens in the emmetrope; a weak convex glass may be required for distance, and a stronger one for near work since the accommodation has been sacrificed. The operation does not seem to increase or decrease the danger of complications. Suitable cases present themselves much less frequently in America than in Germany, where myopia is very common.

ASTIGMATISM.

Astigmatism (As.) is that refractive condition of the eye in which there is a *difference in degree of refraction in different meridians*, so that each will focus parallel rays at a different point (Figs. 293–297).

In E., H., and M., rays coming from a luminous point are brought to a single focus at a certain distance behind the cornea. In astigmatism, since the refractive surfaces are not spherical, rays from a luminous point are brought to a focus

at different points; the shape of the image may be a line, an oval, or a circle, but never a point.

Astigmatism may be (1) *Irregular*, comparatively infrequent, and (2) *Regular*, very common.

IRREGULAR ASTIGMATISM is that variety in which there is not only a difference of refraction in different meridians, but also in *different parts of the same meridian*. It is generally due to *changes in the cornea*, such as opacities and cicatrices following ulceration, injuries, or surgical operations, and keratoconus. It may also result from partial dislocation of the *lens*, or from a congenital or acquired change in the refractive power of different sectors of the lens. The acuteness of *vision* is considerably *diminished* and *cannot be improved materially by glasses*. Details of the *fundus* when seen with the ophthalmoscope appear *distorted*. An insignificant amount of irregular astigmatism is present normally, and accounts for our seeing the stars as stellate points instead of round dots.

REGULAR ASTIGMATISM is that form in which, though the refraction in a meridian is the same throughout, there is a *difference in the degree of refraction in every meridian*. In other words, the curvature of the cornea is different in the different meridians. One meridian exhibits the *maximum* and the other the *minimum* refraction; these are called the *principal meridians* and are *always at right angles* to each other. The refractive power of all other planes will be regularly intermediate according to their position with regard to the principal meridians.

When the term astigmatism is used without qualification, it refers to regular astigmatism.

Etiology.—Astigmatism is usually due to a *change in the curvature of the cornea*, with or without some shortening or lengthening of the antero-posterior diameter of the eyeball. It is also caused, in part at least, by defects in the curvature of the lens; this *lenticular astigmatism* may partly neutralize that of the cornea. It is usually *congenital* and there is often an *hereditary* tendency. It may, however, be *acquired*, and is then caused by corneal changes resulting from inflammation, injury, or operation. Pressure of the lids in ametropia

is sometimes believed to be capable of producing permanent regular astigmatism.

Even the normal eye has a slight amount of regular astigmatism, due to the fact that the cornea is the segment, not of a sphere, but of an ellipsoid; consequently there is a slight difference in the refraction of the two principal meridians, the curvature of the vertical meridian being greater than that of the horizontal; hence the focus of the former is somewhat shorter than that of the latter.

Refraction of Rays in Regular Astigmatism.—Parallel rays refracted by a spherical surface form a circular cone and come to a focus at a point. In astigmatism, those rays which pass through the meridian of greater curvature come to a focus sooner than those which pass through the meridian of lesser curvature, and the resulting cone will not be circular, but more or less oval; hence the vision of astigmatic subjects is not simply indistinct, but the diffusion images are more or less elongated.

In looking at straight lines (which are made up of a succession of points), these may appear distinct or indistinct to astigmatic persons according to their direction. If an astigmatic eye, in which the vertical meridian is out of focus and the horizontal meridian normal, looks at a vertical line, this will be slightly elongated; but the sides will appear distinct, since

FIG. 291.

FIG. 292.

FIG. 291.—Vertical and Horizontal Lines as Seen by an Astigmatic Eye in which the Horizontal Meridian is Emmetropic.

FIG. 292.—Vertical and Horizontal Lines as Seen by an Astigmatic Eye in which the Vertical Meridian is Emmetropic.

each point of light will be seen as a small vertical line, and these overlap each other. But if such an eye looks at a horizontal line, each point of light will again be seen as a small vertical line, and consequently the line will appear blurred (Fig. 291). There is, therefore, one direction in which straight lines appear most distinct, and another at right angles to it, in which they appear most indistinct; this forms the basis for the construction of the *astig-*

matic dial or fan (Fig. 298) commonly used as a test for this error. The lines parallel with the ametropic meridian are seen most clearly, and those parallel with the emmetropic meridian are seen most indistinctly (in simple As.).

Varieties of Regular Astigmatism.—According to the refraction of the principal meridians, astigmatism is divided into:

1. *Simple*, in which one meridian is emmetropic and the

FIG. 293.—Simple Hyperopic Astigmatism. FIG. 294.—Simple Myopic Astigmatism.

other hyperopic or myopic; it comprises simple hyperopic astigmatism (H. As., Fig. 293), and simple myopic astigmatism (M. As., Fig. 294).

2. *Compound*, in which both meridians are either hyperopic

FIG. 295.—Compound Hyperopic Astigmatism.

FIG. 296.—Compound Myopic Astigmatism.

or myopic, but unequal in degree; it comprises compound hyperopic astigmatism (H. + H. As., Fig. 295), and compound myopic astigmatism (M. + M. As., Fig. 296).

3. *Mixed*, in which one meridian is hyperopic and the other myopic (H. As. + M. As., Fig. 297).

In most cases of astigmatism, the cornea presents its *maximum curvature* in or near the *vertical meridian* and the least curvature in or near the *horizontal meridian*, corresponding to the slight astigmatism of the normal eye; when this is the case, it is said to be *astigmatism with the rule*;

when the relative curvatures are reversed, it is *astigmatism against the rule*. In astigmatism with the rule the axis of

FIG. 297.—Mixed Astigmatism.

the cylinder is vertical or nearly so in hyperopic astigmatism, and horizontal or nearly so in myopic astigmatism. The chief meridians, though *vertical* and *horizontal* in the majority of cases, may occupy an

oblique position; in such cases they are most frequently *symmetrical*, i.e., inclined an equal number of degrees from the vertical or horizontal on each side.

Symptoms.—There is always a *diminution in the acuteness of vision* both distant and near, the amount depending upon the degree and variety of astigmatism; it is least with simple astigmatism, more with compound astigmatism, most with mixed astigmatism. There is commonly considerable *asthenopia*, especially upon use of the eyes for near work. These asthenopic symptoms are similar to those occurring in hyperopia (p. 290), but are apt to be more pronounced and more continuous. They vary with the degree and variety of astigmatism, the amount of near work indulged in, and especially the state of the patient's health; a small amount (0.50 D. or even 0.25 D.) will, for instance, often give rise to severe asthenopic and nervous symptoms in a young, delicate, neurasthenic individual. The involuntary accommodative efforts of the ciliary muscle, made to diminish the effects of the error, cause continuous *eye strain* and explain the frequency of asthenopia.

Tests.—We usually *suspect astigmatism* when the vision cannot be brought up to $\frac{20}{20}$ with spherical lenses, notwithstanding the fact that the fundus is normal and the media are clear. In testing for astigmatism in children and in young adults, sometimes even in adults of forty, and occasionally after this age, it is necessary to have the eye under the influence of a *cycloplegic*; otherwise the results are apt to be unsatisfactory.

The Astigmatic Dial.—The diagnosis of astigmatism is made if the patient when placed before the astigmatic dial or fan (formed of radiating lines numbered like the face of a clock, Fig. 298), is unable to see all the lines with equal distinctness. The line seen most distinctly and the line seen least distinctly indicate the axes of the two principal meridians; the axis of the former corresponds to the ametropic meridian, that of the latter to the emmetropic meridian (in simple astigmatism).

FIG. 298.—Astigmatic Dial.

Suppose in an example of simple astigmatism, the patient sees lines *XII* and *VI* most distinctly and those at right angles, *IX* and *III*, least clearly; then the ametropic meridian is vertical. If we place a weak convex lens in front of the eye, and find that this makes lines *XII* and *VI* indistinct, we know that the horizontal meridian is emmetropic. Next we find which spherical lens clears up lines *IX* and *III*; this glass is the measure of the refractive error of the vertical (ametropic) meridian.

The Metal Disc with Stenopæic Slit (about 1 mm. in diameter) may be used to discover the *two principal meridians* (and the amount of astigmatism). It is placed in front of one eye, the other being excluded, and is rotated slowly so that the slit occupies each meridian successively. The patient is placed at 20 feet before the distant test types and the position of the slit in which the best vision is obtained is noted. Then convex or concave lenses are placed in front of the slit, and the strongest convex or the weakest concave lens which gives the most improvement is the measure of the refraction in this meridian. The slit is then turned 90°, and convex and concave lenses are again applied until one is found which improves vision most. In this way the refractive error of the two principal meridians is determined. If, for instance, when the slit is vertical the patient reads $\frac{20}{20}$, and convex lenses in front of the slit make the types indistinct, the vertical merid-

ian is emmetropic; if, when the slit is horizontal, the patient reads $\frac{2}{5}\%$, but this increases to $\frac{2}{2}\%$ when $+3$ D. Sph. is placed in front, the horizontal meridian is hyperopic 3 D.; this case would be one of simple hyperopic astigmatism corrected by a $+3$ D. cylinder, axis vertical.

The Subjective Method with Test Types and Test Lenses is best employed after the objective tests have furnished us with pretty definite conclusions regarding the correcting lenses. It then serves to confirm or improve upon the results obtained by objective methods: The lenses selected by the latter tests are placed in the trial frame and may then require modification, either in the strength of the sphere or the strength and axis of the cylinder, so as to secure the most acute vision.

The Ophthalmoscope, Indirect Method.—The shape of the disc is *oval* instead of circular, and changes when the objective lens is withdrawn.

The Ophthalmoscope, Direct Method.—The disc appears oval, the elongation corresponding to the meridian of greatest refraction, and is at right angles to the long axis of the oval seen with the indirect method. To determine the kind and amount of error we estimate the refraction of a small vertical blood-vessel and then of a small horizontal vessel near the disc, by means of the strongest convex or the weakest concave lens with which these are distinctly seen. For instance, suppose a vertical vessel is seen clearly with $+2$ D. Sph. (indicating hyperopia of horizontal meridian), and a horizontal vessel with $+4$ D. (indicating a greater amount of hyperopia in the vertical meridian); the case is one of compound hyperopic astigmatism. When the principal meridians are oblique, we find a vessel the direction of which corresponds to one of the meridians, and then another at right angles to the first, and estimate the refraction of each.

Retinoscopy is the *most rapid and reliable* objective method of determining astigmatism. The principal meridians are clearly indicated by the edge of the shadow (Fig. 279). Each of the principal meridians is corrected separately by causing a reversal of the movement of the shadow by spherical lenses, and adding -1 D. (with plane mirror at 1 metre distance).

The *Ophthalmometer* (Fig. 299) is an instrument used for determining the principal meridians and the amount of *corneal astigmatism*. It is of service when used in connection with other tests. It consists of a telescope containing a combina-

FIG. 299.—The Ophthalmometer.

tion of convex lenses and a bi-refracting prism, supporting a graduated arc upon which are two sliding objects called "mires" (Fig. 300). The latter are of white enamel, one quadrilateral in shape, the other of similar size but cut out on one side into steps; both are divided in the middle by a horizontal black line. The patient's face is placed in a frame at the other end of the instrument and steadied by chin and forehead rests. The mires are reflected upon the cornea, and the observer, looking through the tube and focussing, sees four images in a line. The two peripheral images are ignored; the two central ones are approximated until their inner edges touch and the black lines subdividing the mires form one continuous straight line; it may be necessary to revolve the barrel of the telescope more or less of 45° to the right or left to

accomplish this. This position, indicated on a dial, gives the meridian of least refraction. Next the arc is turned at right

FIG. 300.

FIG. 301.

FIG. 300.—The Mires of the Ophthalmometer Indicating an Absence of Corneal Astigmatism.

FIG. 301.—The Overlapping of the Mires of the Ophthalmometer Indicating 1 D. of Corneal Astigmatism.

angles to this meridian. If the images of the mires are still in apposition, the curvature of the cornea is uniform and there is no corneal astigmatism (Fig. 300). If in the second meridian the relative position of the images of the mires has changed, each step which is overlapped by the

quadrilateral figure indicates 1 D. of astigmatism (Fig. 301).

Placido's Disc or *Keratoscope* (Fig. 6) consists of a circular disc upon which are painted alternate rings of black and white. The patient is placed with his back to the light and fixes the centre of the disc, while the examiner looks through an opening in the centre and sees an image of the concentric circles reflected upon the patient's cornea. If no astigmatism is present the rings are circular (Fig. 302). If regular astigmatism exists, the rings will appear elliptical with the long axis corresponding to the meridian of least curvature (Fig. 303). If the cornea is the seat of irregular astigmatism the rings will be distorted (Fig. 304). This forms a very useful *qualitative* test.

FIG. 302.

FIG. 303.

FIG. 304.

FIG. 302.—Corneal Reflection of Placido's Disc in Emmetropia.

FIG. 303.—Corneal Reflection of Placido's Disc in Regular Astigmatism.

FIG. 304.—Corneal Reflection of Placido's Disc in Irregular Astigmatism.

If regular astigmatism exists, the rings will appear elliptical with the long axis corresponding to the meridian of least curvature (Fig. 303). If the cornea is the seat of irregular astigmatism the rings will be distorted (Fig. 304). This forms a very useful *qualitative* test.

The Correction of Astigmatism.—Astigmatism is corrected by cylinders, sphero-cylinders, and sometimes by crossed cylinders (p. 266). The curve of the correcting cylinder corresponds to the ametropic meridian; consequently its axis is at right angles to this meridian.

Treatment consists in prescribing *glasses* which correct the error. In many cases of moderate or high degree it is impossible to obtain V. $\frac{2}{3}$ even with the full correction; we often

have to be satisfied with $\frac{2}{3}0$ or $\frac{2}{4}0$. But the vision often improves after the lenses have been worn for a time. The glasses should be *worn constantly*. When the correction has been estimated with the eye under the effects of a cycloplegic, a slight reduction must be made in cases of moderate or high degrees of astigmatism; after a while, the full correction will be tolerated. The relief which cylinders give is usually very pronounced.

The Direction of the Axis of a Cylinder is indicated according to two systems:

FIG. 305.—Ordinary Method of Designating the Axis of Cylinders.

(1) By the angle which the axis makes with the horizontal, this angle being numbered from 0° on our right (as we stand before the patient) to 180° on our left (Fig. 305); *i.e.*, 0° is placed at the end of the horizontal meridian to the patient's left, and the degrees are counted on the upper semicircle to 180° at his right (either eye).

FIG. 306.—Bisymmetrical Method of Designating the Axis of Cylinders.

(2) The position of the axis is denoted by the angular deviation of the upper end of the cylinder from the vertical meridian, either on the nasal or the temporal side. The vertical meridian is indicated by *V*, the horizontal meridian by *H*, the

angles on the temporal side by t , and those on the nasal side by n . Thus, $30n = 30^\circ$ toward the nasal side; $60t = 60^\circ$ toward the temporal side, from the vertical meridian (Fig. 306).

ANISOMETROPIA.

This term is applied to cases of *marked inequality in the state of refraction of the two eyes*; slight differences are present in most cases of errors of refraction. Every possible combination may occur: (1) One eye may be emmetropic and the other ametropic. (2) both eyes may have the same variety of ametropia, but of unequal degree; (3) one eye may be myopic and the other hyperopic, either simple or combined with astigmatism. Notwithstanding the unequal refraction, there is usually binocular vision; sometimes the eyes are used alternately; and in other cases one eye is habitually excluded from vision.

In prescribing glasses no arbitrary rules can be followed; *each case must be considered by itself*. When one eye is emmetropic and the other ametropic, no glass will probably be required, unless it be to prevent the ametropic eye from suffering from disuse, or for the relief of asthenopic symptoms. When the difference in the refraction is not great (1 to 2 D.) and there is good binocular vision, we may give each eye its correction. Even when the difference is greater, correcting lenses will often give satisfaction; but when full correction causes discomfort we must be satisfied with a partial correction. When there is no binocular vision, we generally give a correcting glass for the better eye. In such cases, if the poor eye still possesses vision, the patient should be advised to exercise it daily with the aid of a suitable lens, the good eye being excluded, so that the amblyopic eye may retain its vision and the defect prevented from becoming worse.

ASTHENOPIA.

Asthenopia (*Weak Sight* or *Eye Strain*) is a convenient term which embraces the group of symptoms dependent upon *fatigue of the ciliary muscle or of the extraocular muscles*.

Symptoms.—The condition is of *very frequent* occurrence and causes a great *variety* of symptoms. The most common manifestations of asthenopia are: (1) *Pain* in or around the eyes or *headache*, usually aggravated by use of the eyes for close work, and in some cases present only after near use. (2) *Fatigue and discomfort* upon use of the eyes for near; this shows itself by inability to indulge in such work for more than a short period at a time, without the occurrence of dimness of vision and confusion of the lines of print, pain in and about the eyes, headache, drowsiness, lacrymation, photophobia and congestion, and an irritable condition of the lids accompanied by itching and burning sensations. These symptoms are regularly *worse at night*, when the patient is *tired*, or when *artificial illumination* is employed. (3) *Vertigo* and a tendency to diplopia. (4) *Reflex symptoms*, such as nausea, twitching of the facial muscles, migraine, chorea, neurasthenia, and possibly other neuroses.

The amount of asthenopia depends not only upon the kind and degree of defect, but also upon the *state of the patient's health*, and is therefore pronounced in delicate, anæmic, and neurasthenic individuals.

Varieties.—1, Accommodative. 2, Muscular. 3, Neurasthenic. Two of these varieties may be associated.

Accommodative Asthenopia is the most common variety. It is due to strain and *fatigue of the ciliary muscle* when used too constantly or excessively, in *ametropia*. It is especially frequent in astigmatism and hyperopia, but is common enough in myopia and in presbyopia. *Treatment* consists in the use of glasses correcting the error of refraction as advised in preceding pages. In delicate and neurasthenic individuals attention to the *general health* is very important.

Muscular Asthenopia is due to a want of balance of the motor apparatus of the eye (*heterophoria*), necessitating an abnormal strain to preserve single binocular vision. It may be associated with ametropia and its existence be dependent upon the latter error, or it may occur in emmetropia. Heterophoria is fully described in Chapter XXV.

Neurasthenic Asthenopia (*Nervous, Hysterical, or Retinal*

Asthenopia) is the variety which occurs in emmetropic patients, or in ametropes in whom proper correcting lenses and treatment of any existing heterophoria give no relief. The symptoms are ascribed to *lack of nerve-tone*; occasionally they are supposed to be due to retinal anæsthesia or hyperæsthesia. The condition is a neurosis and is dependent upon a general asthenic condition of the nervous system; consequently it is found most frequently in young women with hysterical tendency, who suffer from anæmia, neurasthenia, and often menstrual disorders; also in neurasthenic individuals in general, and in convalescents from debilitating diseases. It is often very *troublesome* and frequently *obstinate*. The more carefully one investigates the state of refraction and the motor balance of the eye, the fewer cases one finds necessary to classify as neurasthenic. *Treatment* consists in removing the defect in the *general condition*, rest of the eyes, and particularly *attention to hygiene*, such as the regulation of habits, outdoor *exercise*, etc.

MYDRIATICS AND CYCLOPLEGICS.

The action of these agents and the method of obtaining the best results with them are described in Chapter XXVI.

A cycloplegic is *indicated* in the estimation of the refraction in all cases of children and young adults, in many cases between the ages of 35 and 45, and occasionally between 45 and 50 when the previous investigation of the refraction without paralysis of accommodation has been unsatisfactory. Before using these agents in elderly persons, any *suspicion of glaucoma* must be excluded.

Homatropine (two-per-cent. solution), or homatropine, two per cent., combined with cocaine, one per cent., is the agent most frequently employed; one drop is instilled every five minutes for four doses, and the examination begun at the end of half an hour after the last instillation.

Exceptionally, homatropine fails to produce complete paralysis of accommodation, as shown by more or less contradiction in the results of the objective and subjective tests. In such

cases, particularly in children, we may resort to atropine (one-per-cent. solution), one drop being instilled three times daily for two or three days (smoked glasses may be worn during this period), and a final drop directly before the examination.

In children and in young adults, it is proper to make one examination without a mydriatic, a second under the influence of homatropine, and then to base the prescription for glasses upon a comparison of these results, according to the rules given in the preceding pages.

THE FITTING OF EYEGLASSES AND SPECTACLES.

Much of the comfort and relief which lenses bring will depend upon the skill with which the glasses are *fitted to the face*. Whether eyeglasses or spectacles are worn, the lenses must be supported in their frames in such a manner that the distance between their geometric centres corresponds to the interval between the centres of the pupils (*interpupillary distance*).

If the glasses are to be worn constantly, the geometrical centre of the lenses should be slightly below the centre of the pupils, and the lenses *tilted* so that their surfaces form an angle of about 15° with the plane of the face. If worn for distance only, the level of the lenses should be the same and the tilting about 10° . If worn for near work only, the lenses should be lower, and inclined about 25° .

In every case the glasses should be worn as *near the eyes* as possible, just avoiding the lashes.

Lenses are usually made of crown glass. The *periscopic* form of spherical lenses (p. 257) is preferred. In *cylinders*, one surface is generally plane and the other curved; but such lenses can also be ground with two curved surfaces, the cylinder corresponding to the outer surface. *Sphero-cylinders* usually have the spherical lens on one surface and the cylindrical lens on the other. In *toric lenses* both the cylindrical and spherical curves are ground on the outer surface, the inner being deeply concave; this gives an enlarged field and reduces the weight and thickness of the lens. Lenses cut from

crystal are known as *pebbles* ; they have the advantage of being less easily scratched.

In cases of *astigmatism*, it is necessary that the *axis of the cylinder be constant*. On this account spectacles are often preferred to eyeglasses, because with the latter, the axis of the

FIG. 307.—Bifocal Lens (Oval Paster).

FIG. 308.—Bifocal Lens (Circular Paster).

cylinder may vary according to how the glasses are worn or how they preserve their original adjustment. But eyeglasses can be worn in such cases, if the optician exercises sufficient skill in fitting.

FIG. 309.—Section of the Invisible Bifocal Lens.

consists of an oval or circular segment cemented to the lower portion of one surface of the distance glass (Figs. 307 and 308). The *invisible bifocal lens* is constructed of two blades of crown glass, between which the presbyopic segment is inserted before they are cemented together (Fig. 309). The increased strength of the smaller lens depends upon the higher refractive index of flint glass of which it is made. These lenses are very neat and are achromatic, but they are expensive.

Bifocal Lenses consist of an upper portion of one focus, and a lower part of another. They are used principally in cases of *presbyopia associated with ametropia*, the lower portion being used for reading and near work, and the upper for distance. The bifocal lenses most often used are those in which the addition

CHAPTER XXIV.

ANOMALIES OF ACCOMMODATION.

UNDER this heading are included presbyopia, paralysis of accommodation, and spasm of accommodation.

PRESBYOPIA.

Presbyopia (*old sight*, Pr.) is a *physiological change* which affects every eye, commencing *between the 40th and 45th years*, as a result of which the *near point recedes* beyond the distance at which we are accustomed to read ordinary print; this distance has been fixed somewhat arbitrarily at 22 cm. (about 9 inches). The change is due chiefly to *loss of elasticity of the lens*, whereby it is prevented from responding to the action of the ciliary muscle; consequently the *power of accommodation is lessened*. As explained on p. 273, this diminution in the power of accommodation begins early, about the 10th year. Between the 40th and 45th years it becomes sufficient to interfere with the comfortable exercise of near vision; then presbyopia is said to be present.

At the age of 40, there are 4.5 D. of accommodation, and the near point is at 22 cm. or 9 inches. To read at 9 inches, such an individual would require all of his accommodation and the effort would soon become fatiguing, since only one-half or two-thirds of this power can be used for any length of time without causing asthenopic symptoms. Generally, however, the adult holds print at about 13 inches (33 cm.), requiring 3 D. of accommodation and leaving a reserve of 1.50 D.; this is usually sufficient to insure comfort. At 45 his accommodation has diminished to 3.5 D.; all or nearly all of this would be required to read comfortably at 13 inches, leaving little or no reserve. If he keeps one-third of his accommodation in reserve, he will have about 2.25 D. available for

near work; with this, his reading distance would be 45 cm. or 18 inches—too great for comfortable and continuous near work. Hence we must supply the defect in the power of accommodation by a convex lens sufficient to bring the near point back to a convenient distance.

Symptoms.—The presbyope is compelled to hold reading, writing, sewing, and other forms of near work *farther* away than the usual distance, making such efforts *uncomfortable*. With this recession of the near point beyond the usual situation, the *print becomes pale and indistinct*, and fine type can be read only with great difficulty. The patient is apt to use strong illumination; this produces contraction of the pupil, and thus improves the definition by diminishing the circles of diffusion. If the condition be uncorrected, he suffers from *asthenopic symptoms*, especially pain, fatigue, lacrymation, dimness of vision, and irritation of the lids, all of these symptoms being more marked in the evening with *artificial illumination*. Presbyopia has *no effect upon distant vision*.

Treatment consists in prescribing *convex spherical lenses for near work* so as to compensate for the lack of power of accommodation, and to bring the near point back to a comfortable working distance, about 13 inches.

We can generally prescribe the correcting glasses *according to age*. The rule is to give + 1 D. at 45, and to add 1 D. for every five years; this will bring the near point back to 22 cm. or 9 inches:

Age 45,	glass required	+ 1 D.
" 50,	" "	+ 2 D.
" 55,	" "	+ 3 D.
" 60,	" "	+ 4 D.
" 65 and over	" "	+ 4.50 D.

The numbers just given are somewhat arbitrary; frequently we will find that a *slightly weaker lens* will be sufficient. The *age* at which patients are obliged to wear glasses *varies* within a few years, and is influenced, to a certain extent, by the vigor of the individual; a delicate or neurasthenic person will require glasses for reading earlier than a robust individual.

The glasses must also be selected with reference to the *occu-*

pation or the *special use* for which the patient wishes them. Thus in reading, writing, and sewing, 13 inches (33 cm.) is a comfortable working distance for most persons; but a musician may prefer a distance of 20 inches (50 cm.), and consequently he will require a weaker glass.

To find the glass required, we note the patient's near point; then we estimate the lens which represents this point; finally we subtract this number from the lens whose focus corresponds to the distance at which the patient desires to work. For example, suppose the near point has receded to 50 cm. (20 inches); this is represented by a + 2 D. lens ($\frac{100}{50}$ or $\frac{40}{20} = 2$). We wish to bring the near point to 33 cm. (13 inches), which corresponds to + 3 D. ($\frac{100}{33}$ or $\frac{40}{13} = 3$). Hence + 2 D. from + 3 D. = + 1 D., the glass required.

The existence of *ametropia* will modify the strength of glasses required for presbyopia. Hence the patient's vision for distance, and the state of his refraction, must be determined before estimating the glasses required for near work. In any case of ametropia the *lenses required for distance must be added* to those which would be selected for presbyopia in the emmetrope. This would have the effect of increasing the strength of the convex lens required for presbyopia in cases of hyperopia, and of diminishing its power in myopia. For example, suppose a patient of 50 has hyperopia of 1.50 D.; his glasses for reading would be H. 1.50 + Pr. 2 D. = + 3.50 D. A myope of 2 D. will require no glass at 50, since - 2 D. and + 2 D. (Pr.) neutralize each other. At 55, he would require + 1 D. instead of the usual = 3 D. (- 2 D. + 3 D. = + 1 D.). If the myopia amounts to 5.00 D., the patient will never require glasses for reading, since his far point will always be 20 cm. or 8 inches. In astigmatism, the cylinders must be added to the convex lenses required for the correction of presbyopia.

Since presbyopia increases with age, the glasses will require *changing* for stronger ones *every few years*. When the glasses have to be changed for stronger lenses very frequently, we should suspect *glaucoma* and examine the eye carefully for this disease.

PARALYSIS OF ACCOMMODATION.

Paralysis of Accommodation (*Cycloplegia*) is a *partial* (par-esis) or *complete loss of power in the ciliary muscle* due to paralysis of the *third nerve*, or of that branch of the motor oculi which supplies the ciliary muscle and iris. Though occasionally confined to the ciliary muscle, the paralysis usually includes the sphincter pupillæ. When limited to the ciliary muscle and iris, it is known as *ophthalmoplegia interna* (p. 331).

Etiology.—The most frequent cause is the use of *mydriatics*, such as atropine and homatropine. It may be part of a complete *paralysis of the third nerve*. It occurs not infrequently after *diphtheria*. Other causes are *contusions* of the eyeball, debilitated states of the system, grippe, syphilis, diabetes, and cerebral disease.

Symptoms.—These are *loss of power of accommodation and dilatation of the pupil*. If emmetropic, the patient will have good vision for distance but will be unable to do near work without convex glasses. If hyperopic, both near and distant vision will be impaired. If myopic, the patient will be able to see only at his far point; he may therefore be able to do without his accommodation, if the myopia is considerable.

Prognosis is usually *good*, especially when the affection is due to syphilis, diphtheria, or the use of a mydriatic. In traumatic cases the condition may be permanent.

Treatment.—We attempt to *remove the cause* of the paralysis: In syphilis, *specific treatment* is indicated. In post-diphtheritic paralysis, and in that due to debilitated conditions, tonics are given, especially *strychnine*. *Locally*, the *miotics* (eserine or pilocarpine) are employed. These cause contraction of the pupil and of the ciliary muscle, producing spasm of accommodation, and temporarily relieve the symptoms; the alternate contraction and relaxation of the ciliary muscle often stimulate it to action. The local application of electricity is sometimes useful. In traumatic cases, complete rest is indicated, in addition to the remedies just mentioned. If the paralysis has lasted some time, *convex glasses* may be given for near work.

SPASM OF ACCOMMODATION.

Tonic spasm of the ciliary muscle is frequently met with in children and in young adults ; it occurs generally in *hyperopia*, but it may accompany E. or any error of refraction.

Etiology.—It is usually due to long-continued application of the eyes for near work, especially when the young patient is in poor health, has uncorrected ametropia, and the work has been excessive and done with poor illumination.

Symptoms.—*Both eyes* are usually affected. There are *asthenopic symptoms* and *diminished acuteness of vision*. In emmetropia, the spasm gives rise to the signs of myopia; in hyperopia, it reduces the amount of manifest error and increases the proportion of latent hyperopia, or it may even cause the patient to appear myopic; in myopia the error is increased. The diagnosis is made after instilling a cycloplegic; in some of these cases homatropine is insufficient and *atropine* must be used.

Treatment consists in the *abstinence from near work*, the *correction of ametropia*, attention to the *general health*, and the production of paralysis of accommodation for a few days or weeks by instillations of *atropine*.

CHAPTER XXV.

DISTURBANCES OF MOTILITY OF THE EYE.

Anatomy and Physiology.—The eyeball is moved by six muscles, the *extrinsic muscles*, consisting of the four straight and the two oblique; these arise from the wall of the orbit and are inserted into the sclera.

The Recti (*internal, external, superior, inferior*) arise from the circumference of the optic foramen at the apex of the orbit, run forward surrounding the optic nerve and posterior portion of the eyeball, and are inserted into the sclera by means of flattened tendons about 10 mm. wide. The lines of insertion of these muscles are not equidistant from the cornea, but have somewhat the form of a spiral; that of the internal rectus is 5 mm., of the inferior rectus 6 mm., of the external rectus 7 mm., and of the superior rectus 8 mm., from the cornea.

The Superior Oblique arises from the border of the optic foramen, runs forward to the upper and inner angle of the orbit, at the anterior extremity of which it passes through a fibrous pulley; it then continues outward, passing beneath the superior rectus, and is inserted into the upper part of the sclera behind the equator. *The Inferior Oblique* arises from the superior maxillary bone at the inner portion of the lower border of the orbit, passes outward below the inferior rectus, and is inserted into the outer part of the sclera behind the equator.

The muscles are ensheathed by the fascia of the orbit, *Tenon's capsule*, which also covers the sclera and sends prolongations to the walls of the orbit which serve to fix the eyeball in its place. These prolongations are most prominent upon the internal and external recti muscles; they serve to restrain the excursions of the eyeball and are known as "*check ligaments*."

Nerve Supply.—The *third* nerve (oculomotor) supplies all the muscles except the external rectus, which is innervated by the *sixth* (abducens), and the superior oblique, which is supplied by the *fourth* (trochlearis). The nuclei for these three nerves are found in the floor of the fourth ventricle.

Action of the Muscles.—The six extrinsic muscles serve to rotate the eyeball around a *vertical, transverse, and antero-posterior axis*, the centre of rotation corresponding approximately to the centre of the eyeball, and the movements being free in all directions, like a ball-and-socket joint. The movements

which take place about the vertical axis are *adduction* (toward the nose) and *abduction* (toward the temple); about the transverse axis, *elevation* and *depression*; and about the antero-posterior axis, *wheel rotation* or *torsion*, by means of which the upper extremity of the vertical meridian is inclined inward or outward.

The External Rectus moves the eyeball outward.

The Internal Rectus moves the eyeball inward.

The Superior Rectus moves the eyeball upward, inward, and turns the upper extremity of the vertical meridian inward.

The Inferior Rectus moves the eyeball downward, inward, and turns the upper end of the vertical meridian outward.

The Superior Oblique rotates the upper end of the vertical meridian inward, and moves the eyeball downward and outward.

The Inferior Oblique rotates the upper end of the vertical meridian outward, and moves the eyeball upward and outward.

Movements of the Eyeball.—In every movement of the eyeball *several muscles act at the same time*, as follows: .

Adduction :	{	Internal Rectus. Superior Rectus. Inferior Rectus.	Abduction :	{	External Rectus. Superior Oblique. Inferior Oblique.
-------------	---	--	-------------	---	--

Elevation :	{	Superior Rectus. Inferior Oblique.	Depression :	{	Inferior Rectus. Superior Oblique.
-------------	---	---------------------------------------	--------------	---	---------------------------------------

Rotation of upper extremity of vertical meridian <i>inward</i> .	{	Superior Oblique. Superior Rectus.
---	---	---------------------------------------

Rotation of upper extremity of vertical meridian <i>outward</i> .	{	Inferior Oblique. Inferior Rectus.
--	---	---------------------------------------

Both eyes always move simultaneously (*associated movements*). This association is regulated by centres of association which innervate certain muscles or groups of muscles of the two eyes simultaneously. The associate or conjugate movements occur either in the same direction, with the *visual lines parallel*, or with the lines inclined toward each other (*convergence*).

The Field of Fixation corresponds to the *limits of movement of the eyeball in different directions*, without moving the head. It is best estimated by the perimeter (Fig. 18). The patient's head is fixed so that the eye under examination is opposite the

centre of the instrument. A short word printed with small test-letters is moved along the arc of the perimeter, from the periphery to the centre, until the patient can name the word. The movements must be made with the eye alone, without any change in the position of the head, and the other eye must be covered. The field of fixation in the normal eye is about 45° upward, inward, and outward, and about 60° downward. A special instrument known as Stevens' Tropometer may be used for the determination of the rotations of the eyes.

Binocular Vision and Diplopia.—Under ordinary conditions, both eyes are concerned in the act of vision, and are involuntarily adjusted, so that the image of an object is focussed on the macula of each eye. The two images are then fused into a single mental perception. This faculty constitutes *binocular single vision*, and is controlled by the sense of *fusion*, the origin of the impulse being the fusion centre of the brain.

When images fall on symmetrical points of the two retinae, a single visual sensation is produced (*binocular single vision*). When the visual lines of the two eyes are not directed toward the same object, *i.e.*, when one eye deviates, *diplopia* or *double images* result, unless the image of the deviating eye is disregarded or suppressed. The diplopia is proportional to the amount of deviation. The image which corresponds to the eye which "fixes" the object is distinct, because it lies at the macula, and is known as the *true image*; the image of the deviating eye is less distinct, because it is perceived by a peripheral part of the retina, and is known as the *false image*.

Objects which are situated to the right of the point of fixation throw their images to the left of the macula; and those placed to the left of the point of fixation form images to the right of the macula. In the same manner objects above or below the point of fixation cast their images below or above the macula respectively. By reversing this process *we judge of the situation of an object, and place it at the extremity of an imaginary line drawn from the retinal image through the nodal point*. This process is known as *projection*, and is learned by experience. It enables us to judge of the relative positions of

objects. An object which forms its image to the right of the macula is situated to our left; one which throws its image below the macula is situated above, etc.

If an eye is deflected, an object situated straight ahead will form its image on either side of the macula, and following out this process of projection, it will be referred to the opposite side of the outside world.

Diplopia is said to be *homonymous* when the false image is on the same side as the deviating eye, and *crossed* when it is on the opposite side.

In Fig. 310, the right eye is turned in, and consequently binocular diplopia results. The patient sees a true image

FIG. 310.—Deviation of the Right Eye Inward. Homonymous Diplopia. *TI*, True Image; *FI*, False Image; *m*, Macula.

FIG. 311.—Deviation of the Right Eye Outward. Crossed Diplopia. *TI*, True Image; *FI*, False Image; *m*, Macula.

with the left eye, the image of the candle forming at the macula and being referred to its proper place, *TI*. In the right eye, on account of the deviation inward, the image is thrown upon the retina to the left of the macula and consequently is projected to the right, at *FI*. The image of the right eye being to the right of the image of the left eye, the case is one of *homonymous double images*.

In Fig. 311, the right eye turns out and double images result. The image of the candle lies on the macula in the left eye, and this eye refers the image to its right position; a true image is seen at *TI*. In the right eye, because of its outward deviation, the image falls to the right of the macula and is consequently projected to the left, at *FI*. The images having

crossed in their relative positions, that of the right eye being seen to the left of the image of the left eye, the case is one of *crossed diplopia*.

Double images may also be produced without any deviation, by placing a *prism* in front of the eyes. The prism will deflect the rays so that instead of falling upon the macula, they reach the retina to one side of it.

Varieties of Ocular Deviations.—Deviations from perfect muscular adjustment comprise:

1. *Paralysis*, a deviation in the visual axes due to actual loss of motion in one or more of the ocular muscles; it may be *complete* or *partial*; in the latter case, it is known as *paresis*.

2. *Strabismus* (*Squint* or *Heterotropia*), a decided manifest deviation due to *absence of binocular fixation*, which it is impossible for the patient to overcome.

3. *Heterophoria* (*Insufficiency*), a *tendency* to slight deviation, which is *latent*, due to the *absence of binocular equilibrium*, and habitually corrected by muscular effort prompted by the desire for binocular vision.

The eyes are properly *balanced*, or in a state of *equilibrium*, when the visual lines meet at the object toward which they are directed. This condition is brought about by harmoniously distributed innervation of the muscles; it is known as *orthophoria*. Any disturbance of this muscular equilibrium causes a lack of balance or an "*imbalance*." In speaking of errors of this sort, we always take *both eyes* into consideration.

In *heterophoria*, one eye deviates under cover; but when both eyes are used, the desire for single vision prompts a conveyance of increased innervation to the defective muscle or muscles, and this causes the visual lines to meet exactly at the object to which they are directed. The eyes are then placed in a condition of *forced equilibrium* by the expenditure of an amount of nervous force which frequently causes symptoms of *muscular asthenopia*. Under ordinary circumstances, therefore, the deviation is not apparent; hence it is called *latent deviation*.

In *squint*, the deviation cannot be overcome by increased

innervation; the error is *manifest*. There is a distinct difference between squint and heterophoria; occasionally, under certain circumstances, the latter may change to temporary or permanent squint.

Both of these conditions are differentiated from *paralysis* by the fact that in the latter affection there is complete or partial loss of power in one or more of the muscles.

PARALYSIS OF THE OCULAR MUSCLES.

Symptoms.—1. *Limitation of Movement* of the eye on the side and in the direction of action of the paralyzed muscle; this is pronounced in complete paralysis and less marked in paresis. It can generally be recognized when the patient keeps his head fixed and tries to follow the examiner's finger moved in different directions. If merely a paresis, the defective movement may be so limited that the diagnosis must be made from the nature of the diplopia.

2. *Paralytic Squint*.—When the eyes are turned in the direction of the sphere of action of the paralyzed muscle, the sound eye will be directed properly, but the affected eye will refuse to move, and will squint. The deviation is generally apparent, but more marked the farther the eyes are moved in the direction of the paralyzed muscle. When the eyes are turned in the opposite direction, in which the paralyzed muscle need not participate, there is no squint.

The deflection of the squinting eye is known as the *primary deviation*; it is always in the direction opposite to the normal action of the paralyzed muscle. If the affected eye be made to fix an object and the sound eye be covered, the latter will squint in a corresponding direction, and much more than the affected eye; this deflection of the sound eye is known as the *secondary deviation*. The excess of secondary deviation over the primary is due to the fact that the strong impulse of innervation required to enable the paralyzed eye to fix, being simultaneously transmitted to the associated muscle of the sound eye, produces an overaction of this muscle, and consequently a greater amount of squint. This is an important point in distinguish-

ing between paralytic and concomitant squint; in the latter, the primary and secondary deviations are equal.

3. *Oblique Position of the Head.*—The patient turns his head toward the side of the paralyzed muscle and in the direction in which the paralyzed muscle would, if acting, move the eye. This is done so as to diminish or correct the diplopia. Hence there is a *characteristic position of the head for every variety of paralysis*.

4. *False Projection.*—The paralyzed eye does not see objects in their correct location. The false projection is due to markedly increased innervation, conveyed to the nerve supplying the paralyzed muscle in an effort to force it to act; this gives the patient an erroneous idea of the position of the eye. It can be demonstrated by closing the patient's sound eye and telling him to point quickly at an object in front of him; the finger will be directed to the side of the object corresponding to the paralyzed muscle.

5. *Diplopia* occurs when the patient looks at an object situated *within the sphere of action of the paralyzed muscle*, and becomes more marked the more the eyes are moved toward this side. The presence or absence of diplopia, the relative position of the double images, and the increase or diminution of the distance between them in different parts of the field of fixation, form the most important means of diagnosing the seat of the paralysis.

Method of Testing for Diplopia: This is done by means of a *lighted candle* held at about 10 feet in front of the patient, and moved about in different positions of the field of fixation. For convenience of record and study a diagram is used, consisting of two horizontal and two vertical lines, forming nine spaces (Figs. 312 to 317). The patient must keep his head fixed and merely move his eyes. A *red glass* is placed before one eye so as to distinguish its image. The candle is moved about in different positions of the field of fixation, and the nature of the diplopia noted in each of the nine spaces. The data required are: (1) in which position of the field there is *single vision* and in which *diplopia*; (2) whether the diplopia is *homonymous* or *crossed*; (3) the relative *distance between*

the double images ; (4) whether the two images are on the same or on different *levels* ; and (5) whether the images are *erect* or *inclined*.

The false image is situated in the direction of the normal action of the paralyzed muscle, and the distance between the double images increases in this direction, and diminishes in the opposite direction. In fact, *most of the symptoms*—the limitation of movement, the false image, the turning of the face and oblique position of the head, the faulty projection, and the increase in the distance between the double images—are *in the direction of the normal action of the paralyzed muscle*. The squint, absence of diplopia, and diminution in the distance between the two images, are the only symptoms occurring in the opposite direction.

6. *Vertigo, nausea, and uncertain gait* are frequent symptoms, dependent upon the diplopia and the false projection; they are relieved when the patient closes the paralyzed eye. On this account, patients frequently keep the affected eye closed or covered.

After paralysis has lasted a long time, the symptoms become less characteristic. The diplopia disappears because the image of the deviated eye is *suppressed*, faulty projection is corrected by newly acquired experience, and there occurs *contracture of the antagonist* of the affected muscle, increasing the squint.

When one muscle only is paralyzed, the diagnosis is easy; but when several muscles are involved, it is often difficult to determine the exact combination.

Varieties of Ocular Paralysis.—One muscle may be involved, or several muscles in various combinations may be affected. Paralysis of the external rectus is the most common; that of the superior oblique is frequent; isolated paralysis of the remaining four muscles is much less common. Combined paralysis of some or all of the four muscles supplied by the third nerve is exceedingly common.

Paralysis of the External Rectus (Sixth Nerve).—There is limitation of movement outward; convergent squint; and the face is turned toward the paralyzed side. Homonymous diplopia upon looking tow-

ard the paralyzed side; the images are on the same level and parallel (slightly tilted in the upper or lower portions of the field); the lateral separation increases with abduction of the paralyzed eye (Fig. 312).

FIG. 312.—Paralysis of the External Rectus (the dotted outline refers to the false image).

Paralysis of the Internal Rectus.—There is limitation of movement inward; divergent squint; the face is turned toward the sound side. Crossed diplopia, on looking toward the sound side; the images are on a level and parallel (slightly tilted in upper and lower portions of field);

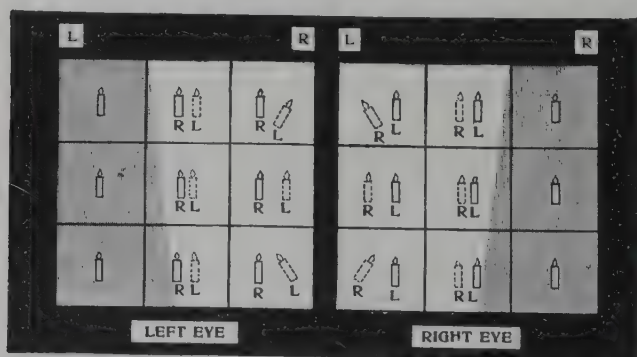

FIG. 313.—Paralysis of the Internal Rectus (the dotted outline refers to the false image).

lateral separation increases with adduction of the paralyzed eye (Fig. 313).

Paralysis of the Superior Rectus.—There is limitation of movement upward and toward the sound side; deviation of the eye downward and a little outward, with the vertical meridian inclined toward the temple;

the face is directed upward and toward the sound side, and the head inclined toward the shoulder of the healthy side. Crossed and vertical diplopia upon looking up; the false image is higher and its upper end

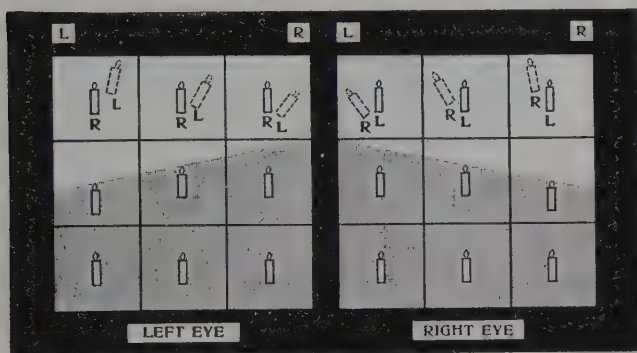

FIG. 314.—Paralysis of the Superior Rectus (the dotted outline refers to the false image).

inclined toward the nose; the vertical distance between the images increases and the inclination of the false image diminishes, upon looking upward and toward the paralyzed side (Fig. 314).

Paralysis of the Inferior Rectus.—There is limitation of movement downward and toward the sound side; deviation of the eye upward

FIG. 315.—Paralysis of the Inferior Rectus (the dotted outline refers to the false image).

and slightly outward, with the vertical meridian inclined toward the nose; the face is directed downward and toward the sound side, and inclined toward the shoulder of the paralyzed side. Crossed and vertical diplopia on looking down; the false image is lower, and its upper

end inclined toward the temple; the vertical distance between the images increases and the inclination of the false image decreases, upon looking downward and toward the paralyzed side (Fig. 315).

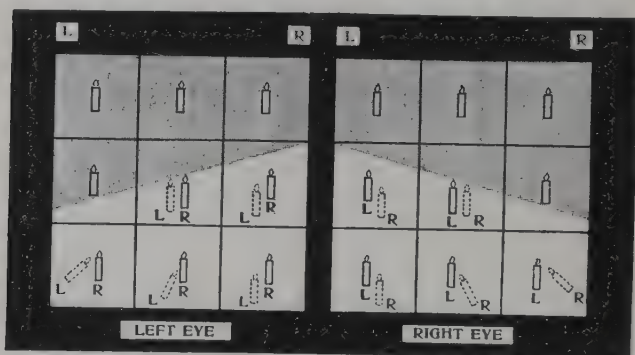

FIG. 316.—Paralysis of the Superior Oblique (the dotted outline refers to the false image).

*Paralysis of the Superior Oblique (Fourth Nerve).—*There is limitation of movement downward and toward the paralyzed side; the eye is deviated upward and slightly inward, with the vertical meridian inclined toward the temple; the face is directed downward and toward the sound side, and the head is inclined over the shoulder of the sound side.

FIG. 317.—Paralysis of the Inferior Oblique (the dotted outline refers to the false image).

The patient has great difficulty in moving about, especially in going down-stairs. Homonymous and vertical diplopia on looking down; the false image is lower and its upper end inclined toward the sound side; the vertical distance between the images increases, and the incli-

nation of the false image decreases upon looking downward and toward the sound side (Fig. 316).

Paralysis of the Inferior Oblique.—There is limitation of movement upward and toward the paralyzed side; the eye is deviated downward and slightly inward, with the vertical meridian inclined toward the nose; the face is directed upward and toward the paralyzed side, and the head is inclined toward the affected side. Homonymous and vertical diplopia on looking up; the false image is higher and its upper end inclined toward the temple; the vertical distance between the images increases, and the inclination of the false image decreases upon looking upward and toward the sound side (Fig. 317).

The Diagnosis of the Particular Muscle or Muscles Paralyzed in any case in which we analyze the diplopia is often

FIG. 318.—Werner's Diagram showing the Nature of the Diplopia in Paralysis of the Superior and Inferior Recti Muscles.

FIG. 319.—Werner's Diagram showing the Nature of the Diplopia in Paralysis of the Superior and Inferior Oblique Muscles.

difficult, on account of the different actions of the orbital muscles. Werner's diagrams (Figs. 318 and 319) will serve as a mnemonic aid in this respect:

"The form of diplopia which characterizes paralysis of each muscle is expressed by the position of the dotted line bearing the name of the muscle. The dotted lines represent the false images, the continuous lines the true images.

In the case of the recti (Fig. 318) the false images enclose a lozenge-shaped space situated between the true ones, whereas in the case of the oblique muscles (Fig. 319) the true images, which for the sake of simplicity are combined in one line, lie between the four false images, which diverge from one another so as to form an X. It will also be noted that the dotted lines extend upward and downward beyond the others, indicating respectively that the false images are higher or lower

than the true ones. Another fact which the diagrams indicate is that in the case of the muscles represented in the upper halves of the figures, the diplopia occurs in the upper part of the field of fixation, or, in other words, in upward movements of the eyes. A similar rule holds good with regard to the lower halves.

The method of using the diagrams will be better understood by taking a particular muscle as an example. Suppose, for instance, that we wish to know what kind of diplopia results from paralysis of the left inferior rectus, it is simply necessary to look at the left inferior portion of Fig. 318 (recti), which gives the diplopia. If we analyze this, we find: 1. That the diplopia is crossed, for the false image corresponding to the left eye is on the right of the true image—*i.e.*, the right image corresponds to the left eye. 2. That the false image has its upper end inclined toward the true one. 3. That the false image is lower than the true one, for the dotted line extends lower than the other one. 4. That the diplopia occurs in downward movements of the eyes, for it is in the lower half of the diagram that the false image lies.

The same rules apply to the obliques (Fig. 319), with one difference. The recti move the eye in the direction indicated by their names, the superior moving it upward and the inferior downward; but in the case of the obliques the reverse takes place, the superior oblique moving the eye downward and the inferior upward. Therefore for the superior obliques we must look at the lower half of the figure, and for the inferior obliques at the upper part.

By bearing the figures in mind it is possible to tell immediately what kind of diplopia would result from paralysis of any one of these muscles, and conversely, given the diplopia, to determine to which muscle it is due."

Paralysis of the Third Nerve.—With complete paralysis of this nerve there is *ptosis*; the *eyeball is almost immobile*, the limitation of movement being upward, downward, and inward; the eye *deviates outward* and somewhat downward, with the upper end of the vertical meridian inclined inward, especially upon looking downward; the face is directed upward and toward the sound side, and the head inclined to the shoulder of the paralyzed side. There is *slight exophthalmos* on account of the paralysis of the three recti which normally draw the eyeball backward; the *pupil is dilated* and is *immobile*; *accommodation is paralyzed*; there is crossed *diplopia*—the false image is higher, and its upper end inclined toward the paralyzed side.

Paralysis of the third nerve is *common*; it is *often incom-*

plete, two or three of the muscles being affected. It may be associated with paralysis of other nerves.

When all the muscles of one eye are paralyzed, including the iris and ciliary body, the condition is known as *total ophthalmoplegia*.

When all the exterior muscles of the eyeball are paralyzed, but not the iris and ciliary body, the condition is known as *external ophthalmoplegia*. This form is more common than total ophthalmoplegia; the nuclei for the sphincter pupillæ and ciliary muscle being separate, they often escape involvement of processes affecting the origin of the exterior ocular muscles. This form of paralysis is generally of central (nuclear) origin.

When only the sphincter pupillæ and the ciliary muscle are paralyzed, the condition is known as *internal ophthalmoplegia* (p. 316).

Associated or Conjugate Paralysis involve associated muscles, such as the external rectus of one eye and the internal rectus of the other; they are due to lesions in the association centres.

Etiology.—The lesions causing paralysis may be situated anywhere in the course of the nerve tract, from the cerebral cortex to the muscle. According to its site, the lesion is distinguished as *central* and *peripheral*. *Central lesions* may be situated in the cortical centres (*cortical paralysis*), the *association* centres, the nuclei of origin (*nuclear paralysis*), or in the fibres which connect these centres. *Peripheral lesions* may affect the nerves in some part of their course, either between the point where they issue from the brain and their entrance into the orbit (*basilar paralysis*), or in the nerve or its branches in the orbit (*orbital paralysis*).

The Differential Diagnosis between Central and Peripheral Paralysis is not always easy; it is based on the character of the paralysis and the accompanying symptoms. Complete paralysis, unaccompanied by any other symptoms, is generally peripheral. When central, the paralysis is generally less complete, more than one muscle is usually involved, there are apt to be cerebral symptoms, and there is commonly an absence of peripheral cause.

The Nature of the Lesion.—The lesion may be either a neighboring exudation, hemorrhage, periostitis, tumor, injury, or vascular change, causing compression or inflammation of the nerves; less frequently it is a primary inflammation or degeneration.

The most common cause is *syphilis* (late symptom). Other causes are *rheumatism* and gout, exposure to cold, *diphtheria*, *locomotor ataxia* and other spinal affections, tuberculous meningitis and other cerebral affections, diabetes, acute infectious diseases, toxic affections, and injuries. Occasionally paralysis is congenital.

Prognosis varies with the cause. Peripheral paralyses due to syphilis, rheumatism, and cold usually get well, but there may be *relapses*. In the paralysis accompanying serious spinal and cerebral disease, the prognosis is often bad. Long-neglected paralyses present an unfavorable prognosis, on account of the atrophy of the paralyzed muscle and the contraction of the antagonist. The *course* is always *chronic*, and even in favorable cases, several weeks or months are required to effect a cure.

Treatment should, in the first place, be *directed to the cause*. In syphilis, mercury and large doses of potassic iodide are given. In rheumatism and gout, salicylate of sodium, iodide of potassium, and colchicum, singly or combined, are prescribed. In diphtheria, strychnine is indicated. In obscure cases, potassic iodide with or without mercury is usually resorted to. Hot baths and diaphoresis are sometimes employed.

Locally, we may use massage, electricity, muscle-stretching, ocular-muscle exercises, prisms, and occlusion of one eye. In incurable cases, operative intervention is resorted to.

Massage, applied either directly upon the affected muscle or through the lids, is a simple procedure which is sometimes of value, especially when a single muscle is involved.

Electricity may be tried; the constant current (2 milliamperes) is used, the negative pole being applied to the back of the neck, and the positive over the affected muscle.

When the paralysis remains obstinate, *muscle-stretching* may

be used. Under local anæsthesia, the conjunctiva over the insertion of the paralyzed muscle is seized with a fixation forceps, and the eye forcibly rotated to and fro a number of times during two or three minutes, so as alternately to stretch and relax the affected muscle.

The weakened muscle may be *exercised* by allowing the patient to look through a *prism* which almost corrects the diplopia, thus coaxing the paralyzed muscle into action. The same result can be achieved by having the patient move his head until the double images almost coalesce, and then directing him to make a strong effort to fuse them without any further motion of the head. Such exercises are repeated ten times at each sitting, several times a day.

In chronic cases with moderate paresis, *prisms* may neutralize the diplopia and thus add to the patient's comfort. Prisms stronger than 4° for each eye (8° in all) cannot be worn on account of their weight and chromatic aberration.

During the course of treatment, the deviating eye should be *occluded* by a patch or a ground glass in an ordinary spectacle frame, so as to prevent the annoying diplopia.

If the condition persists for a long period in spite of all treatment, and the paralysis seems incurable, *operative treatment* is indicated. This consists in an *advancement* of the paralyzed muscle, combined in many cases with *tenotomy* of the antagonist. The results of this operation are often disappointing, but the cosmetic improvement may be satisfactory.

STRABISMUS.

Strabismus (*Concomitant Squint* or *Heterotropia*) is a *manifest deviation* of the visual line of one of the eyes, due to *absence of binocular fixation*, the two eyes maintaining the same faulty relationship of axes in every direction in which they are turned. The power of the different muscles of the two eyes is usually normal, and the squinting eye follows the other in all its movements, always deviating from the correct position to the same extent, and *the visual lines remaining at the same angle*; on this account, the condition is known as *con-*

comitant squint. It is a condition of faulty co-ordination of the two eyes. The eye which is directed toward the object looked at, is known as the *fixing eye*, the other as the *squinting eye*.

Strabismus differs from *heterophoria*. In the latter disorder the deviation is latent; when both eyes are used, the visual axes are properly directed and kept in a state of forced equilibrium by increased innervation called forth by the desire for binocular single vision. In strabismus, on the other hand, the deviation is manifest, and cannot be overcome by increased innervation.

Strabismus is distinguished from *paralytic squint* by presenting a normal range of movement of each eye, and the same deviation in all parts of the visual field. In paralysis, the deviation is present only in the sphere of action of the paralyzed muscle, and there is limitation of movement in a certain direction. In concomitant squint, the primary and secondary deviations are equal; in paralytic squint, the secondary deviation is greater than the primary. Diplopia is a prominent symptom in paralytic squint, while in concomitant strabismus it is seldom present.

Varieties.—Squint is said to be

1. *Periodic or Occasional*, when present only at times, as after accommodating excessively, or when the system is deranged. This variety may disappear with non-operative treatment, or pass into the constant variety.

2. *Constant*, when always present. Either of these two varieties may be alternating or monocular.

3. *Alternating*, when the patient fixes with either eye indifferently, the vision in the two eyes being about equal; or else one eye fixes for distance, and the other for near vision.

4. *Monocular*, when the same eye habitually deviates; the vision in this eye is usually below that of the other.

According to the *direction of deviation*, squint is divided into—

- (a) *Internal Squint* (*Strabismus Convergens, Esotropia*), the commonest form.

- (b) *External Squint* (*Strabismus Divergens, Exotropia*).

(c) *Vertical Squint* (*Hypertropia*; *Strabismus Sursum Vergens*, when upward; *Strabismus Deorsum Vergens*, when downward); this form is uncommon. Some vertical deviation, usually upward, not infrequently accompanies a convergent squint.

Diagnosis can usually be made, qualitatively, by *inspection*. But in slight degrees this cannot be depended upon. The *cover test* is a simple but rough test made by means of the hand or a card: The patient is directed to fix a distant object and a card is placed alternately over one and then over the other eye. If, when one eye is covered, the other has to make an outward or inward movement in order to fix the object, it was previously squinting inward or outward.

The Measurement of Squint.—The amount of strabismus may be measured by (1) markings on the lower lid, (2) by the strabismometer, and (3) by the perimeter.

The Linear Method presents a simple and fairly accurate measure (Fig. 320). The patient is directed to fix a distant object situated in the median line; the position of the outer margin of the cornea of the squinting eye is marked upon the lower lid margin (*S*, Fig. 320). Next, we cover the fixing eye and tell the patient to look at the same distant object with the squinting eye; as the latter begins to fix and is brought into proper position the location of the outer margin of the cornea is again marked upon the border of the lower lid (*F*, Fig. 320). The distance between the two marks (*FS*) gives the linear measure of the squint. Thus we say a squint of 2 lines, 4 mm., etc.

FIG. 320.—The Measurement of Squint by the Linear Method.

The Strabismometer (Fig. 321) is a small ivory plate, having an upper margin curved to conform to the lower lid, and marked with the inch or millimetre scale, by which the deviation of the centre of the pupil in the fixing and the squinting positions is measured.

The Perimeter (Fig. 18) gives the *angular measurement* of

squint. The patient is seated with the squinting eye in the centre of the instrument, and is directed to fix a distant object placed in the median line, with both eyes. The quadrant is

FIG. 321.—The Strabismometer.

placed horizontal when the squint is convergent or divergent. A lighted candle is now moved along the inside of the arc from the centre outward, until its reflection on the cornea is seen in the centre of the pupil of the squinting eye. The number of degrees on the arc at this point indicates the size of the strabismus angle.

Symptoms.—The *cosmetic disadvantage* is the symptom which usually leads the patient to consult an oculist. There is *no diplopia* except in the very early stages, the double images soon disappearing owing to a psychical process of *excluding* the image of the squinting eye. There is usually *diminution in the acuteness of vision* of the deviating eye. This may or may not have existed previous to the development of strabismus; in either case, it increases with the duration

of the squint as a result of *amblyopia ex anopsia* (from disuse), and may finally become very pronounced. There are no asthenopic symptoms.

Etiology.—Concomitant squint is generally the result of an interference with the normal fusion of the macular images of the two eyes, dependent upon a *defect of the fusion faculty*. In the infant, the motor co-ordinations of the eyes serve to maintain an approximate parallelism of the visual axes. The fusion faculty soon begins to develop and is complete before the sixth year; this establishes a desire for binocular vision which keeps the eyes straight.

“Sometimes, however, owing to a congenital defect, the fusion faculty develops later than it should, or it develops very imperfectly, or it may never develop at all. Then there is nothing but the motor co-ordinations to preserve the normal relative directions of the eyes, and anything which disturbs

the balance of these co-ordinations will cause a permanent squint" (Worth).

In the presence of a defect of the fusion faculty, the eyes are in a state of *unstable equilibrium*, ready to squint on slight provocation. Such *exciting causes* may be (1) disturbance in the relation between accommodation and convergence by *errors of refraction*, (2) *anisometropia*, (3) *imperfect vision* in one eye due to congenital amblyopia, opacities of the media, and intraocular diseases, (4) disparity in the length or thickness of opposing *muscles*.

CONVERGENT CONCOMITANT STRABISMUS.

In this form of squint (esotropia) there is *deviation inward* of the visual line of one eye (Fig. 322). It is generally associated with *hyperopia*, with or without hyperopic astigmatism, this error of refraction being found in at least three-quarters of all cases; occasionally it occurs in myopia and in emmetropia. It usually commences in *early life*, between the *first and fourth years*, when the child begins to use his accommodation for near objects, such as toys and pictures; rarely it is congenital. At first the squint may be noticed only at times (periodic), with near vision, or when there is any interference with the general health; but it is apt to become constant for both near and distant vision; occasionally it disappears.

FIG. 322.—Convergent Strabismus.

The *acuteness of vision* in the squinting eye often presents *considerable reduction*, and there may be marked *amblyopia*. Whether the squint precedes and is the cause of the amblyopia, or whether the amblyopia is originally present and is the exciting cause of the squint, is one of the much-discussed but unsettled questions in ophthalmology. Recent investigations seem to prove that in most instances the *amblyopia is acquired from disuse* of the squinting eye.

The frequent *association of convergent squint and hyperopia* depends upon the intimate connection between *accommodation and convergence*. A child who is hyperopic must use some accommodation for distance, and considerably more for near vision. Since accommodation and convergence are associated, he must increase his convergence with any increase of accommodation. In looking at a near object, the stimulus to converge would correspond not only to the amount present in the emmetrope, but would include an additional and abnormal amount called for by the extra accommodation required to compensate for his hyperopia. Hence the point of convergence is nearer than the distance accommodated for and convergent squint results.

Treatment comprises (1) correction of refractive errors by glasses, (2) exercise of the squinting eye by occluding its fellow, (3) instillation of atropine, (4) training the fusion sense, and (5) operation.

Non-Operative Treatment.—The *error of refraction* should be estimated under *atropine*, and *convex glasses* correcting very nearly the total hyperopia (also the astigmatism, if present) prescribed for *constant wear*. In slight cases, especially if periodic, this sometimes effects a cure. Glasses may be worn by children of two years and upward. It is sometimes advisable to keep the eyes under the influence of *atropine* for a week when the glasses are first worn.

The fixing eye should be covered by a *patch or bandage* for one hour, three times a day, or the occlusion may be continuous. This compels the squinting eye to fix, *exercises it*, prevents amblyopia from disuse, and restores, as far as possible, the sight of the deviating eye if amblyopia already exists.

Atropine should be instilled into the *fixing eye* so that the latter cannot be used for near vision, thus compelling the child to employ the squinting eye for seeing close objects. One drop of a one-per-cent. solution is instilled every morning and the practice may be kept up for months.

Training the Fusion Sense.—Binocular perception and fusion may be trained by *stereoscopes*, but most successfully with *Worth's Amblyoscope* (Fig. 323).

This instrument consists of two brass tubes joined by a hinge, each provided with a mirror and a convex lens. The object-slides consist of devices drawn on translucent paper and gummed on glass squares (Fig. 324). The two halves of the instrument can be brought together to suit

FIG. 323.—Worth's Amblyoscope.

a convergence of the visual axes up to 60° , or separated to suit a divergence of 30° . Each object-slide is illuminated by a separate electric lamp which can be brought nearer or pushed farther away, thus increasing or diminishing the illumination of either of the pictures.

The *Amblyoscope* is used as follows: The instrument is adapted roughly to the angle of the child's squint and the ex-

FIG. 324.—Object-slides used with Worth's Amblyoscope.

ercises are begun by an attempt to develop *simultaneous perception*, by bringing the light before the squinting eye nearer and nearer, and adjusting the relative distances of the lights,

until the objects of both slides are seen simultaneously. Then the child is taught to *fuse* the images. Finally the amplitude of fusion is increased, and the *sense of perspective* taught.

Non-operative treatment of squint is successful in a large proportion of cases of convergent concomitant squint, *if made use of sufficiently early*. The earlier such treatment is begun, the better the results. After the sixth year these procedures are not usually effective.

Operative Treatment.—If non-operative measures do not overcome the deviation in from six months to a year, *operation* is indicated. It is not customary to operate before the *seventh year*, unless the squint be very well marked, although there are competent oculists who advocate operation at a much earlier age. In cases in which it was found impossible to develop the fusion faculty, operation relieves the disfigurement but fails to give binocular single vision.

Two operative procedures, *tenotomy* of an internal rectus, and *advancement* of an external rectus, are employed either singly or in combination. *Tenotomy* of an internal rectus consists in a division of this muscle at its insertion into the globe, allowing the eye to rotate outward. In *advancement*, the tendon is separated from the globe at its insertion, often shortened, and the cut end secured to the eyeball at a point nearer the cornea than the original insertion.

The choice of operation depends upon the amount of squint, the lateral excursions of both eyes, the amount of amblyopia in the squinting eye, and upon other conditions brought out by careful examination. The relative advantages of tenotomy and advancement have been much discussed. *Tenotomy* is much the easier operation, quickly performed, inflicting but little pain when done under local anæsthesia, and causing little inconvenience to the patient. *Advancement*, on the other hand, is more difficult, somewhat painful, often requires a general anæsthetic, and the patient is confined to the house for several days. It is claimed that it is more rational to strengthen a weaker muscle by advancing its insertion, than to weaken a stronger one by tenotomy. A good general rule is to resort to tenotomy when there is considerable overaction of the in-

ternal recti with normal power of the externi, and to advance one or both externi when there is relaxation of these muscles with decided limitation in abduction. Deviations of more than 25° are best corrected by an advancement of the external rectus and a tenotomy of the internal rectus.

The estimation of the result likely to follow operative treatment requires considerable judgment and experience. A free tenotomy of one internal rectus will usually diminish an internal squint to the extent of about 13° (3 to 4 mm.). An advancement, if successfully carried out, will produce any degree of rotation of the globe. As a rule, only one internal rectus should be divided at a time, unless the squint be very marked, since it is difficult to gauge the after-effect correctly. The full effects of such operations frequently are seen only after several months; if too much has been done, there will be divergence. In young children, a general anæsthetic is usually required; in older children, local anæsthesia will suffice.

DIVERGENT CONCOMITANT STRABISMUS.

This form of squint exists when one eye fixes an object and the other *deviates outward* (Fig. 325). It is usually associated with *myopia*; near-sightedness is present in two-thirds of all persons with divergent squint. But it may occur with other errors of refraction. It is also observed after tenotomy for the cure of internal squint, and when the *fusion faculty is defective* or the *sight in one eye is deficient* or abolished, as in opacities of the media, ocular disease and injury, and in *blindness*; in these cases, binocular vision being impossible, there is no need for convergence. Divergent squint is much less frequent than convergent.

Association with Myopia.—In myopia little or no accommodation is needed for near vision; consequently, there is an habitual deficiency of the stimulus for convergence, and a tendency to relax the internal recti muscles. Again, the exces-

FIG. 325.—Divergent Strabismus.

sive convergence necessary to see near objects within the far point causes fatigue of the interni, giving rise to muscular asthenopia (p. 309); to relieve this, one of the internal recti muscles relaxes, and the eye turns out, especially if the sight in this eye is defective. Another predisposing cause of the frequent association of divergent squint with myopia is the increased antero-posterior diameter of the eyeball, which mechanically limits convergence.

Unlike convergent squint, the condition is infrequent in very young children. It *develops during youth*, when near-sightedness is established, and the tendency increases with the degree of myopia. When this error reaches a high degree, the far point is so closely approximated, that it is impossible to maintain the necessary convergence, and divergence becomes inevitable. At first, the squint is manifest only during near use of the eyes (periodic); but it usually progresses and is present in distant as well as with near vision (constant).

Treatment.—In recent cases, when the squint is still periodic and the patient's vision is good, we may cure the squint by giving the *full correcting lenses*. In other cases, especially those of long duration, *operation* is indicated. The best results are obtained from *advancement of one or both internal recti*.

TENOTOMY.

The following description applies to tenotomy of the right internal rectus. The *methods of operating* employed most frequently are the *subconjunctival* (Critchett's) and the *open* (Graefe's).

Instruments Required.—(1) Eye speculum (Fig. 328); (2) a fixation forceps (Fig. 326); (3) toothed forceps (Fig. 327); (4) blunt-pointed, curved strabismus scissors (Fig. 331); (5) two squint hooks (Fig. 330); (6) needle holder (Fig. 333); (7) fine curved and half-curved needles (Fig. 329); and thin black silk.

The Subconjunctival Method.—The speculum is introduced and the eyeball drawn outward, if necessary, by an assistant. The conjunctiva over the lowest portion of the insertion of the muscle, together with the subconjunctival tissue and Tenon's

capsule, is seized with the toothed forceps, raised and divided with scissors; the first cut divides the conjunctiva, the second Tenon's capsule. Keeping the fold raised with the forceps, a strabismus hook is introduced through the opening, passed beneath the tendon, and pushed upward until its point is seen through the conjunctiva at the upper border of the muscle. The hook is transferred to the left hand and raised so as to lift the tendon. The scissors are taken in the right hand and introduced, one branch between the tendon and conjunctiva,

FIG. 334. Tenotomy of the Internal Rectus.

and the other between the tendon and sclera; the tendon is divided close to the sclera by two or more small cuts. The hook is reintroduced to make sure that no portion of the tendon has been left undivided. If the tendon has been completely divided, the hook can be advanced to the cornea without resistance; if not, the undivided fibres must be cut

with scissors. The hook is again introduced and swept from behind forward, above, and below, to ascertain whether there are any uncut fibres of attachment to the sclera which, if found, must be severed. The conjunctival wound is closed with a single vertical suture.

The Open Method.—The steps are the same as in the preceding operation except that the muscle is exposed. The conjunctiva is incised about 2 mm. from the corneal margin, and dissected backward and downward beyond the lower border of the muscle. The hook is inserted beneath the fully exposed tendon, which is raised and divided close to the sclera (Fig. 334). The wound is closed by two vertical sutures.

After-Treatment.—The result of the operation should be noted shortly after completion, if the patient is not under a general anæsthetic; in the latter case, we must wait for this to wear off. It may be necessary to *lessen the effect by a su-*

ture which stitches the muscle forward to the insertion of the tendon; or to *increase the effect* by again introducing the hook and dividing the upper and lower extremities of the insertion of the tendon, or by rotating the eyeball in the opposite direction and keeping it in this position by a suture.

There should always be *some convergence* (5°) *left* after the operation since, although the primary result usually diminishes for a few days, the subsequent effect increases for a number of months or possibly a year. Hence if the immediate correction be perfect, there is apt to be subsequent divergence.

To *increase the effect* of the operation, *atropine* should be instilled and *both eyes bandaged* for a few days. If we do not desire such an increase in correction, this is unnecessary. There is usually no great reaction; the eye is congested, but not painful. The bandage can be left off on the following day. Sometimes there is slight deformity caused by a *sinking of the caruncle*, the result of free division of Tenon's capsule. Infection and suppurative inflammation have occurred in rare instances, emphasizing the necessity for strict asepsis.

ADVANCEMENT OF AN OCULAR MUSCLE.

Advancement *brings the attachment of the muscle forward*. A considerable degree of rotation of the eyeball may be produced. For moderate deviations, it will be sufficient to advance the muscle without tenotomizing the opponent. For squints of high degree, it is best to perform first a *tenotomy* upon the opposing muscle. There are many methods of advancing an ocular muscle. The Worth operation is one of the best and is performed as follows:

Operation: The *instruments* required are the same as those needed for tenotomy, with the addition of a Prince's advancement forceps (Fig. 332). A general anæsthetic is sometimes required, but in many instances *local anæsthesia* will suffice.

The eye is anæsthetized with cocaine or holocain. Adrenalin is instilled before and from time to time during the operation. The lids are held open by the speculum. The surgeon, standing behind the patient's head, grasps the conjunctiva with the toothed forceps, while, with the scissors, he

makes a straight vertical incision through it about half an inch long. The middle of the incision is close to the corneal margin. A similar incision is then made through the capsule of Tenon. The conjunctiva and capsule then retract, or, if necessary, they are pushed back, so as to expose the insertion of the tendon. The smooth blade of a Prince's advancement forceps is now passed under the tendon, after the manner of a tenotomy hook, the toothed blade being superficial to the con-

FIG. 335.—Worth's Operation of Advancement of an Ocular Muscle.

junctiva. The forceps are now closed, so that tendon, capsule of Tenon, and conjunctiva are firmly clamped together, with their relations undisturbed (Fig. 335). The tendon, and a few little fibrous bands beneath the tendon, are now divided with scissors, at their insertion into the sclerotic. The forceps, holding the tendon, capsule, and conjunctiva, can easily

be lifted up so as to get a good view of the under side of the muscle.

Two curved needles are provided with threads which should be thick and preferably prepared by previous boiling in wax. One of the needles is then passed inward at *A* (Fig. 335), through conjunctiva, capsule, and muscle, and brought out at the under side of the muscle. It is then again passed through muscle, capsule, and conjunctiva, and brought out at *B*. The bight of the thread thus encloses about the lower fourth of the width of the muscle, together with its tendinous expansions and capsule and conjunctiva. The other needle is similarly entered at *A'* and brought out through the conjunctiva at *B'*, the bight of this suture thus enclosing the upper fourth of the width of the muscle. The ends of the thread from *A* and *B* are then knotted tightly at *C*. The end bearing the needle is then entered at *D*, and passed through conjunctiva, capsule, and muscle, and carried beneath the lower blade of the forceps nearly to the corneal margin. The needle is here passed through the tough circumcorneal fibrous tissue, and brought out at *G*. The two ends of the thread are temporarily tied loosely, with a single hitch at *H*. The first suture is then similarly completed.

The anterior part of the muscle, capsule, and conjunctiva are removed, by cutting them through with scissors behind where they are grasped by the forceps. The gap is then closed by tightening and securely tying each suture at *HH*, so that the eyeball is rotated in its correct position, and the anterior end of the muscle is brought nearly up to the corneal margin at *GG*. The longitudinal position, on the muscle, of the knotted loops *ABC* and *A'B'C'* varies approximately according to the degree of rotation required.

The eye is bandaged, and the patient kept in bed for twenty-four hours, and confined to his room for two or three days. The stitches are usually allowed to remain in for about a week, unless we wish to diminish the effect of the operation. If properly performed, the immediate effect produced is the final result.

HETEROPHORIA.

Heterophoria (*Insufficiency*) is a condition in which the eyes have a *constant tendency to deviate*, but are forced into simultaneous fixation of an object by special exertion. If this effort were not made, there would be a slight deviation and double images. So as to secure binocular vision and avoid diplopia, *an excessive amount of innervation is employed to maintain proper though forced balance*. When one eye is covered, diplopia cannot occur; hence the eye will deviate; its direction now represents the position of rest. The condition differs from concomitant squint; in the latter affection, the deviation is due to an absence of the power of binocular fixation and cannot be overcome by increased innervation.

Varieties.—The following terms are employed for designating the various forms of heterophoria:

Orthophoria, perfect muscle balance.

Heterophoria, imperfect muscle balance.

Exophoria, a tendency to deviate outward (latent divergence).

Esophoria, a tendency to deviate inward (latent convergence).

Hyperphoria, a tendency of one eye to deviate upward; *right hyperphoria*, when the right eye tends to deviate upward; *left hyperphoria*, when the left eye tends to diverge upward.

Hyperexophoria and *hyperesophoria*, a combination of hyperphoria with exophoria and esophoria respectively.

Cyclophoria, a term introduced by Savage, want of equilibrium of the oblique muscles.

Etiology.—The chief cause is some *error of refraction*, especially when accompanied by some *disturbance in the normal relationship between accommodation and convergence*. Another very common cause is *general lack of muscular tone* seen in delicate individuals and in convalescence from systemic diseases. Much less frequently, certain *anatomical conditions*, such as a defect or weakness, or abnormality in size or insertion of one of the muscles, is responsible. The condition is *very common*.

Symptoms.—In *slight degrees* of heterophoria, there are very often *no symptoms* whatever. In *more pronounced forms*, the symptoms of *muscular asthenopia* are present: Headache, various neuralgias, mental dulness, pain in the eyes, indistinctness or “running together” of print, diplopia, vertigo, and irritable condition of the lids. In *exophoria*, these symptoms are complained of most after use of the eyes for *near* work, in *esophoria* with *distant* vision. Sometimes the patient complains of one eye turning in or out. Not infrequently there is a feeling of ocular soreness in the morning upon awakening. The dependence of epilepsy, chorea, and other serious nervous disorders upon heterophoria is extremely doubtful, but neurasthenia and disturbances of digestion and nutrition may be the result of the muscular error in predisposed individuals.

Tests are usually carried out both at 20 feet and at 13 inches. The best *test object* for distance is a *candle flame*, and for near, a *black spot* (1 to 2 mm.) upon a white card. Since the deviation is latent, its presence is revealed only by certain tests. When the eyes are in a state of *perfect balance*, there is *orthophoria for distance*, and usually a *slight exophoria* (corrected by a prism of 2° to 3°) *for near*.

The Cover Test.—The patient is directed to look at a *distant object* (20 feet), placed in the median line on a level with his eyes. A *card* is placed over one eye, and then over the other alternately, and the examiner notes the position and movement of the eye at the moment of uncovering. If on exposing the right eye and placing the card over the left, the right eye moves in, in order to fix the object, there must have been a deviation outward when covered (*exophoria*). If on being uncovered the eye moves out, there is *esophoria*. If when the right eye is uncovered it moves down, there is right *hyperphoria*; if it moves up, there is left *hyperphoria*.

The test is repeated for a *near object* (a pencil, for instance) held in the median line and on a level with the patient's eyes, at about 13 inches.

The amount of movement of readjustment is proportional to the degree of deviation. Deviations of 2° or more are readily discovered by this test.

The Fixation Test.—The patient is directed to fix a small object, held in the median line on a level with the patient's eyes, and slowly advanced toward the patient's nose, to within two inches. If there is weakness of the interni (*exophoria*), one of the eyes will deviate outward before this convergence near point is reached.

FIG. 336.—Maddox Rod.

The Maddox Rod is a piece of glass rod set in a hard-rubber disc, so as to fit into the trial frame (Fig. 336). It converts the image of the flame perceived by one eye into a long streak of light (Fig. 337), so that there remains no desire

to unite it with the image of the other eye. The line is always at right angle to the axis of the rod.

The Maddox rod is placed *horizontal* before the right eye, converting its image of the candle flame into a vertical streak. If *orthophoria* is present, this streak appears to pass directly

FIG. 337.

FIG. 338.

FIG. 339.

FIG. 337.—The Maddox Rod Test in Orthophoria.

FIG. 338.—The Maddox Rod Test in Exophoria.

FIG. 339.—The Maddox Rod Test in Esophoria.

through the image seen with the other eye (Fig. 337). If the line of light appears to the left of the flame, there is crossed diplopia, indicating *exophoria* (Fig. 338); if to the right of the flame, there is homonymous diplopia, indicating *esophoria* (Fig. 339). The amount of heterophoria is measured by the prism, base in or out, which serves to displace the streak until it runs directly through the flame.

The rod is then placed *vertical* before the right eye, converting the image of this eye into a horizontal line of light, which will pass through the image of the left eye (Fig. 340) if *orthophoria* prevails. If this is below the image of the flame seen

FIG. 340.

FIG. 341.

FIG. 342.

FIG. 340.—The Maddox Rod in Orthophoria.

FIG. 341.—The Maddox Rod in Left Hyperphoria.

FIG. 342.—The Maddox Rod in Right Hyperphoria.

with the left eye, there is *right hyperphoria* (Fig. 342); if above, there is *left hyperphoria* (Fig. 341). The degree of hyperphoria is measured by the prism, base up or down, which causes the light streak to pass directly through the flame.

Any *strong convex cylinder* will answer the same purpose. The Maddox rod is sometimes made of red glass, or a piece of red glass is held in front of one eye, so as to color one image and thus effect a still greater reduction in the tendency to fuse the two images. A piece of *red glass* held in front of one eye is sufficient in itself to cause diplopia, whenever the heterophoria is marked.

FIG. 343.

FIG. 344.

FIG. 345.

FIG. 343.—The Graefe Test, Orthophoria.

FIGS. 344 and 345.—The Graefe Test, Heterophoria.

The *Graefe Test* consists in placing a *prism of 10°*, base up or down, before one eye, thus *causing vertical diplopia*. If there is orthophoria, one image of the flame at 20 feet appears

directly below the other. But if there is heterophoria, a lateral separation of the images is added to the vertical displacement caused by the prism. A second prism, base in or out, which brings one image exactly over the other, is the measure of the heterophoria.

This test is frequently used for estimating the disturbance of equilibrium with *near vision*. A black dot (2 mm.), and a vertical line 2 or 3 inches long passing through its centre, are drawn upon a white card. The latter is held at 13 inches, and a prism of 10° , base up or down, is placed before one eye. If there is *orthophoria*, the double images of the dot will appear one above the other (Fig. 343); if *heterophoria*, they will be displaced laterally, and there will be two dots and two lines (Figs. 344 and 345). The prism, base in or out, which brings them in the same vertical line is the measure of the deviation.

The *Phorometer* (Fig. 346) furnishes a rapid and convenient means of applying the *Graefe test*. It consists of a pair of 4° prisms. The latter are first placed with their bases up and down so as to produce vertical diplopia. If the double im-

FIG. 346.—The Stevens Phorometer (the base and upright have been omitted from the illustration).

ages do not appear one exactly over the other, there is exophoria or esophoria. By rotation of the prisms, the images can be brought in a vertical line, and the degree of rotation required read off on an attached arc indicates the amount of exophoria or esophoria. Hyperphoria is determined in a sim-

ilar manner, the prisms being placed with their bases in. The test object for near is a small metal plate, in the centre of which is a small opening or cross.

Risley's Rotary Prism is another convenient instrument for the examination of muscular errors.

It is important to *measure the power of the muscles* in adduction, abduction, and sursumduction, as expressed by the strongest prism which can be overcome. *Adduction* or *prism convergence* is determined by ascertaining the strongest prism, base out, which the eyes can overcome—*i.e.*, converge so as to prevent diplopia; in normal eyes this amounts to a prism of 20° to 30° . *Abduction* or *prism divergence* is determined by the strongest prism, base in, which the eyes can overcome; it is represented normally by a prism of 6° to 8° . The usual relationship between adduction and abduction is about 3 to 1; the power of adduction can, however, be increased by practice. *Sursumduction* or the power of *vertical divergence* is measured by the strongest prism, base up or down, that can be overcome; it is usually represented by a prism of 2° or 3° .

Treatment consists in correction of the error of refraction, attention to the general health, prism exercises, the wearing of prisms, and as a last resort, operation.

1. *Correction of the Refractive Error* is of the greatest importance, and frequently is curative. In esophoria the full and constant correction of hyperopia is indicated. In exophoria, a partial correction of the hyperopia, so as to favor accommodation and divergence, is often advisable. In exophoria it is important fully to correct any myopia, and to direct such glasses to be worn constantly, if possible.

2. *Attention to the General Health* is a necessary and valuable adjunct to local treatment. *Tonics* (especially strychnine), hygienic improvement, regulation of habits, and partic-

FIG. 347. Risley's Rotary Prism.

ularly plenty of *outdoor exercise* are indicated, especially in neurasthenic and delicate individuals.

3. *Prism Exercises* serve to strengthen adduction and abduction.

In *exophoria*, prisms with bases out are supported before the patient's eyes, and he is directed to look at a lighted candle placed 20 feet distant. As soon as the double images come together, the prisms are lifted, and after a rest of a few seconds they are replaced. Commencing with 5° , the strength of the prisms is increased every few days, until the patient can easily fuse the double images produced by a pair of 20° prisms. The exercises are continued for a few minutes, several times a day. Whenever there is difficulty in bringing the double images together, the patient must approach the light until the fusion is easily accomplished, and then gradually increase the distance from the candle.

In *esophoria*, if symptoms persist after suitable correction of the error of refraction, prism exercises, bases in, may be tried; they offer, however, less chance of success than in *exophoria*.

In *hyperphoria*, prism exercises, base down or up, are sometimes beneficial.

4. *The Wearing of Prisms* is indicated if correction of the refractive error, improvement in general health, and ocular muscle exercises have failed to relieve the symptoms. The strength of the prisms prescribed should correspond, as a general rule, to about *half the deviation*, though sometimes a full correction gives comfort. The wearing of prisms does not correct the deviation, but may remove the discomfort. Only *weak prisms* can be worn, since those of greater strength than 4° cause chromatic aberration and are uncomfortably heavy. In *exophoria* the bases are turned in, in *esophoria* out, in *hyperphoria* up or down. The wearing of prisms is frequently *unsatisfactory* and the relief is often merely *temporary*. Such correction should not be continued for too long a time, since it usually causes an increase in the deviation.

If lenses are worn, the *effect of a prism* may be obtained by *decentering* the lenses—that is, displacing the optical centre so

that it no longer corresponds to the geometrical centre of the glass (Figs. 348 and 349). *Decentering a convex lens in*, or a *concave lens out*, produces the effect of a *prism with its base toward the nose*; decentering a convex lens up or a concave lens down gives the effect of a prism with its base up. A lens of 1 D. must be decentered 8.7 mm. to produce the effect of a

FIG. 348.

FIG. 349.

FIG. 348.—The Prismatic Effect of Decentering a Convex Lens. A, Convex lens decentered downward; B, optical centre corresponds to geometrical centre.

FIG. 349.—The Prismatic Effect of Decentering a Concave Lens. A, Concave lens decentered downward; B, optical centre corresponds to geometrical centre.

prism of 1° . To calculate the amount of decentering necessary to produce a certain prismatic effect, we multiply 8.7 by the value of the prism, and divide the result by the strength of the lens in diopters. For example, a $+4$ D. lens \subset prism

of 2° , base in, equals $\frac{8.7 \times 2}{4} = 4.3$ mm.; such a lens should

be decentered inward 4.3 mm. in order to have the added effect of a prism of 2° base in.

5. *Operation* should be resorted to only as a *last resort*, after all other measures have been tried and the affection continues troublesome, because we can never be sure of the result. *Disappointment* often follows, and an *aggravation* of symptoms with added and annoying diplopia is not infrequent after operation for the correction of latent deviation. As a general rule, operation is contraindicated unless the *deviation is considerable*, and unless the wearing of prisms has seemed to prove the dependence of the symptoms upon the heterophoria. A *limited or partial tenotomy* may be done upon one or both muscles which seem to overact, or a *limited or partial advancement* upon one or both antagonists. The latter operation is

less apt to prove disappointing and mischievous, and is, consequently, the safer.

Partial Tenotomy and Partial Advancement.—In these operations a small opening is made into the conjunctiva over the insertion of the tendon. In *tenotomy*, the central portion of the tendon is seized and cut, and this incision extended toward both borders, leaving the peripheral portions intact; the effect is measured after each cutting, until the result is sufficient. In *advancement*, the central portion of the tendon is dissected from the eyeball and stitched forward. The instruments used resemble those employed for ordinary tenotomies and advancements, but are of more delicate construction. These operations, though practised quite frequently, are criticised unfavorably by many oculists; the effect is *uncertain*, and the operation must be *repeated* a number of times before a decided result is obtained.

NYSTAGMUS.

Nystagmus is a short, rapid, involuntary *oscillation of the eyeball*, usually affecting *both eyes* and associated with *imperfect vision*. The movements are most frequently from side to side (*lateral nystagmus*) or around the antero-posterior axis (*rotatory nystagmus*), sometimes up and down (*vertical nystagmus*). There may be a combination of the lateral or vertical with the rotatory movements (*mixed nystagmus*). The oscillations are similar in kind, duration, and frequency in the two eyes. They may be constant or present or exaggerated only when the eyes are turned in certain directions. The patient is *not*, as a rule, *inconvenienced* by the existence of this condition; but when it commences in adult life there may be much annoyance from the apparent movements of objects.

Most cases exist from *infancy*, and depend upon diminution in the acuteness of vision or *amblyopia* as a result of opacities of the media, intraocular diseases, albinism and other congenital anomalies, and very marked errors of refraction; in such instances the affection is due to defective vision, which prevents the infant or child from learning to perform fixation properly.

In adults it may develop with many *cerebral affections*, especially disseminated sclerosis. It is also found in coal miners (*miner's nystagmus*); in these cases it is due to working in a recumbent position, requiring the eyes to be turned upward and obliquely, thus causing considerable strain and exhaustion of the ocular muscles.

The usual infantile cases are *not amenable to treatment*, though the condition sometimes becomes less marked with advancing years; the *correction of errors of refraction* may be of some benefit. Miner's nystagmus generally disappears when the patient gives up this kind of work.

CHAPTER XXVI.

OCULAR THERAPEUTICS.

GENERAL RULES FOR EYE OPERATIONS.

THE eye being a very delicate and sensitive organ, it becomes necessary, in applying various therapeutic resources, to limit the strength of local applications and to observe care in the manner in which such remedies are applied.

Remedies employed in the treatment of diseases of the eye may be divided into 1. *constitutional*, and 2. *local*.

Constitutional Remedies are frequently prescribed and often exercise a marked influence on the progress of ocular disease. Many systemic disorders present ocular manifestations; and an important part of the treatment of the latter consists in general medication intended to correct the constitutional disturbance. Syphilis, tuberculosis, anæmia, and other disordered states give well-marked eye symptoms and diseases, which will yield only after proper *internal treatment*. Some ocular diseases are dependent upon a lowering of the general health, for which *tonics* are indicated. *Rest in bed* is often absolutely necessary for the effective control of some of the acute affections of the deeper structures of the eye. Thus it will be evident that the condition of the system cannot be disregarded in the treatment of ocular diseases.

Local Remedies.—Drugs intended for local use to the eye are most frequently *dissolved in water*; a *saturated solution of boric acid* forms a very good menstruum. Such remedies are also used in *ointment, powder, or solid form*.

CLEANSING AND ANTISEPTIC SOLUTIONS.

Solutions of this sort are employed for *washing out the conjunctival sac* and *removing secretion*. They are used *freely*, are

bland and *unirritating*, and should be *lukewarm* when employed. They may be allowed to run between the lids from a wad of *absorbent cotton*, from an *eye-dropper*, using two or three dropperfuls, or poured out very conveniently by means of the *undine* (Figs. 350 and 352), or with a soft-rubber bulb syringe (Fig. 351).

The cleansing and antiseptic solutions which are used most frequently are:

1. *Sterilized Water*.
2. *Boric Acid* in saturated solution (about 4 per cent. ; half an ounce of the crystals to the pint).
3. *Sodium Chloride* in physiological strength (0.6 per cent. ; a teaspoonful to the pint).

FIG. 350.—Undine for Irrigating the Eye.

4. *Mercuric Chloride*, from 1:10,000 to 1:6,000; a grain to the pint.

5. *Formalin*, 1:8,000, a minim to the pint.

6. *Potassium Permanganate*, 1:2,000, 4 grains to the pint.

FIG. 351.—Soft-Rubber Eye Syringe.

Boric Acid (boracic acid) is used more frequently than any other of these remedies. Though chemically an acid, its solution is *bland and soothing*, and is often employed to irrigate the eye during *operations*. It is frequently prescribed with white vaseline, cold cream, or lanolin, in the form of an *ointment*, to prevent adhesion of the lids over night, when

there is considerable discharge.

℞ Acidi borici..... gr. iij.	℞ Acidi borici..... gr. iij.
Vasellini albi..... 3 ij.	Ungt. aq. rosæ 3 ij.
M. ft. ungt.	M. ft. ungt.

It is sometimes dusted into the eye in cases of phlyctenulæ

or ulcers of the cornea; when used for this purpose it must be in the form of a powder in very fine subdivision.

STIMULATING AND ASTRINGENT REMEDIES.

The remedies of this class used most frequently in connection with the eye are: Zinc Sulphate, Tannic Acid, Alum, Borax, Potassium Chlorate, Camphor, Silver Nitrate, Copper

FIG. 352.—Method of Irrigating the Eye with a Solution Poured from an Undine.

Sulphate, Yellow Oxide of Mercury, Ammoniated Mercury, Calomel, and Ichthyol. They are intended to cure abnormal conditions of the conjunctiva, and are used principally in various forms of *conjunctivitis*. For this purpose they are prescribed in *small quantity*. Two or three drops are allowed to fall upon the everted lower lid from an eye-dropper (Fig. 353); the latter must not be allowed to touch the lids or lashes, since this would

lead to contamination, and as a result to infection of the liquid contained in the bottle to which the dropper is returned. Most of these remedies are used in *watery solution*; copper sulphate and alum are frequently employed in *solid form*.

Zinc Sulphate is used very largely in astringent collyria.

R̄ Zinci sulph..... gr. i.
Aque destill..... ʒ i.
M. S. Two drops in each eye
three times a day.

M. S. For the lids.

R̄ Zinci sulph..... gr. i.
Aque camphor..... ʒ x.
Aque destill..... ʒ i.
M. S. Two drops in each eye
twice a day.

Tannic Acid is frequently used in combination with other astringents. It is often dissolved in glycerin, and solutions of 5 to 25 per cent. are painted on the everted lids in trachoma.

℞ Acidi tannici..... gr. ss.
Zinci sulph..... gr. ss.
Aquæ destill..... ℥ i.
M. S. Two drops in each eye
two or three times a day.

℞ Acidi tannici..... gr. ss.
Acidi borici..... gr. v.
Aquæ destill..... ℥ i.
M. S. Two drops in each eye
two or three times a day.

Alum (one-fourth to one grain to the ounce). Long-continued use is said to injure the cornea. Solid alum in the form of a flattened *pencil* is applied to the everted lids in *chronic conjunctivitis*, and in *mild forms of trachoma*.

Borax is used as a cleansing wash (℥ i. to O i.), or in combination with other remedies:

℞ Zinci sulph..... gr. ss.
Sodii biborat..... gr. iij.
Aquæ destill..... ℥ i.
M. S. Two drops in each eye

℞ Acidi tannici..... gr. ¼
Sodii biborat.... gr. iij.
Aquæ camphor..... ℥ iij.
Aquæ destill..... ℥ vi.
M. S. For the lids.

Potassium Chlorate is prescribed in solution, from 1 to 5 grains to the ounce.

Camphor.—Though feebly soluble in water, such solution (aqua camphoræ) is stimulating and astringent, and is often incorporated in collyria.

Silver Nitrate, always dissolved in *distilled water*, may be used in the strength of gr. $\frac{1}{10}$ to gr. $\frac{1}{4}$ to the ounce, *dropped* into the *conjunctival sac*. In *stronger solution* (1 to 5 grains to the ounce) it is *brushed* upon the *everted lids*, in chronic conjunctivitis and in the papillary stage of purulent conjunctivitis. Solutions of nitrate of silver *spoil* upon contact with

FIG. 353.—Method of Instilling Drops by Means of an Eye-Dropper.

organic matter. The brush or cotton applicator should not be dipped into the bottle, but some of the solution should be poured into a small vessel for each use. Silver solutions, when used repeatedly and frequently, *stain* the conjunctiva (*argyrosis*); hence they should be applied by the physician himself, and only for a *limited period*. When stronger than one per cent., they act as *disinfectants* and *caustics* (p. 364).

Copper Sulphate ("bluestone") may be employed in solution (gr. $\frac{1}{2}$ to $\frac{3}{4}$ i.); but its chief use is in the form of the *crystal*. A *flattened pencil* (Figs. 118 and 120) is rubbed across the everted lids (not omitting the retrotarsal fold) in *trachoma*, and the *excess washed off* with water or solution of boric acid. The pencil should be flattened and have a blunt, rounded extremity.

Yellow Oxide of Mercury is insoluble in water; it is employed in the form of an *ointment* made with white vaseline, cold cream, vaseline cold cream, or lanolin. The ointment must be *thoroughly mixed*, and should be preserved in a glass jar which has been coated externally with asphalt varnish so as to be *impervious to light*. Its strength is usually one or two per cent.

R Hydrarg. oxidi flavi... gr. i.
Vasellini albi..... 3 ij.
M. ft. ungt. S. Eye salve.

R Hydrarg. oxidi flavi.. gr. ij.
Ungt. aquæ rosæ.... 3 ij.
M. ft. ungt. S. Eye salve.

These ointments are frequently prescribed and are very useful in *blepharitis*, *chronic conjunctivitis*, *phlyctenular keratitis* and *conjunctivitis*, *interstitial keratitis*, and *opacities of the cornea*. In *blepharitis* the ointment is smeared along the margin of the lid after removal of scales or crusts; in the other affections, a small piece is transferred from the end of a glass rod, blunt instrument, or absorbent cotton firmly wound upon the end of a tooth-pick, to the everted lower lid, and thus into the conjunctival sac.

Ammoniated Mercury is a white, insoluble powder prescribed in the same strength and under the same circumstances as the yellow oxide of mercury.

Calomel occurs in the form of a fine powder, which is dusted

into the eye with a camel's-hair brush in cases of *phlyctenular keratitis* and corneal ulcers. This combination of mercury is thought to change slowly to corrosive sublimate as a result of contact with the tears.

Ichthyol in five- or ten-per-cent. ointment, or mixed with zinc oxide, forms an excellent application for obstinate examples of *ulcerative blepharitis*.

R Ichthyol..... gr. vi.

Vaselini..... 3 ij.

M. ft. ungt. S. Apply to the edges of the lids after cleansing.

R Ichthyol..... gr. x.

Ungt. zinci ox..... 3 ij.

M. ft. ungt. S. Apply to the edges of the lids after removal of crusts.

Lead Acetate should not be employed in connection with the eye. It has the property of depositing an insoluble salt of lead upon any corneal abrasion; this *stain* cannot be removed. Lead and opium wash, so frequently used in other parts of the body, is not, therefore, a desirable application for the eye.

DISINFECTANTS.

True disinfectants (capable of destroying germs) cannot be instilled into the conjunctival sac under ordinary circumstances, since they would injure the cornea. They are, however, applied to *circumscribed areas*, the excess being washed off by some bland solution. *Corneal ulcers*, especially when indolent or *infected*, and *purulent conjunctivitis*, furnish common indications for such use. Some of the remedies classified under this head, though not, strictly speaking, true disinfectants in the strengths in which they are employed, have an inhibitory action upon the growth and development of microorganisms and thus act as *practical disinfectants*. The disinfectants used most commonly in connection with the eye are: Mercuric Chloride, Alcohol, Chlorine Water, Carbolic Acid, Formalin, Tincture of Iodine, Silver Nitrate, Argylol, Protargol, Iodoform, and the Caustery.

Mercuric Chloride (Corrosive Sublimate) is prescribed very frequently in *purulent conjunctivitis*, also in other forms of conjunctivitis. It may safely be used in the strength of 1:5,000; when stronger, it acts unfavorably upon the cornea,

and must consequently be limited in its application to the everted lids, and the excess carefully washed off. A strong solution, 1:500, is rubbed into the conjunctiva after this membrane has been freed from trachoma follicles by the operation of expression. Solutions of corrosive sublimate are often employed to flush the eye during operations; they attack the metal of instruments and dull the cutting edges.

Alcohol is a very efficient disinfectant of the blades of eye instruments.

Chlorine Water diluted with 10 to 20 parts of water is sometimes employed in *purulent conjunctivitis*. It must be *freshly prepared*.

Carbolic Acid (three-per-cent. solution) is used only for disinfecting instruments. Pure carbolic acid is sometimes applied to *infected ulcers* of the cornea.

Formalin.—Solutions of 1:1,000 and 1:2,000 are used in purulent conjunctivitis; solutions of 1:500 are applied to infected ulcers; solutions of 1:200, and formalin vapor, are sometimes employed for the disinfection of instruments.

Tincture of Iodine is an excellent remedy in the treatment of *infected ulcers* (p. 119).

Silver Nitrate is a very efficient and popular disinfectant. In one- or two-per-cent. solution it is applied to the everted lids in purulent and in other forms of *conjunctivitis*, and the excess neutralized by a solution of sodium chloride. In two-per-cent. solution, one drop is instilled into the eyes of the new-born as a prophylactic measure against *ophthalmia neonatorum*. In stronger solution, and in solid stick, it is applied to *infected* and indolent *ulcers*, the excess being neutralized by salt solution. It is fused with potassium nitrate in various proportions, constituting the "*mitigated stick*." For the purpose of producing anæsthesia preliminary to silver applications, solutions of *nitrate of cocaine* should be used instead of the customary hydrochlorate, since the latter alkaloidal salt is incompatible and precipitates chloride of silver, which leaves a permanent stain upon the cornea.

Iodoform is a feeble disinfectant which is sometimes dusted upon *corneal ulcers*, or used in two- to four-per-cent. ointment

in such lesions. It is not infrequently dusted upon wounds after *plastic operations* upon the lids.

Argyrol is an *organic salt of silver*, soluble in water, forming a brown solution. It is used in five- to twenty-five-per-cent. solutions in the same class of cases in which silver nitrate is indicated. It is a decided *germicide*, penetrating, is not precipitated by fluids containing sodium chloride and albumen, and is *devoid of the irritating qualities of silver nitrate*. It does not seem to stain the conjunctiva, even when used for a considerable period.

Protargol has the same properties and uses as argyrol, but has the same tendency to stain the conjunctiva observed with silver nitrate.

The Electro-Cautery (p. 119) gives us the most certain means of limiting the spread of *corneal ulcers*, by destroying the infecting micro-organisms. It is also used in conical cornea, and in epithelioma of the lid.

MYDRIATICS AND CYCLOPLEGICS.

Mydriatics are remedies which produce *dilatation of the pupil*. *Cycloplegics* are agents which cause *paralysis of the ciliary muscle* (paralysis of accommodation). Practically, these two terms are *interchangeable*, since, with two exceptions, the remedies used as mydriatics also produce paralysis of the ciliary muscle.

The drugs which are commonly employed to induce mydriasis and cycloplegia are *atropine* and *homatropine*; very much less frequently we use *duboisine*, *daturine*, *hyoscyamine*, and *scopolamine*.

The remedies employed to produce *dilatation of the pupil*, without practical action on the ciliary muscle, are *cocaine* and *euphthalmin*.

Indications.—Agents of this class are used (1) in *iritis*, for dilating the pupil, preventing adhesions, and exerting a sedative action; (2) in various diseases of the *cornea* and of the *deeper structures of the eye*; (3) after certain *operations*; (4) to paralyze accommodation in estimating the state of *refraction*; (5) to dilate the pupil for *ophthalmoscopic* examination.

tion; and (6) to enlarge the pupil in lamellar and nuclear cataract.

Atropine, the alkaloid of *Belladonna*, is the most commonly employed mydriatic; it is prescribed in the form of *sulphate*. The strength of solution varies from one-half to two per cent.; a *one-per-cent.* solution is used most frequently. Occasionally it is used in the form of an ointment.

R Atropin. sulphat.... gr. i.
 Aquæ destill. 3 ij.
 M. S. *Poison.* One drop in
 each eye every four hours.

R Atropin. sulphat.... gr. i.
 Cocain. hydrochlor.. gr. ij.
 Aquæ destill. 3 ij.
 M. S. *Poison.*

Atropine *paralyzes the sphincter* of the pupil and *stimulates the dilator*. After the instillation of two or three drops at intervals of ten minutes, pronounced action will have taken place in half an hour after the last dose; *the effects last for a week or ten days*. Atropine and other mydriatics (except, generally, cocaine and euphthalmin) *increase intraocular tension*. They are *contraindicated in glaucoma*, and in persons who have a tendency to this disease; we should carefully test the tension in persons past middle life before instilling atropine.

Atropine Poisoning.—In susceptible individuals atropine may cause *general toxic symptoms*: Dryness of the throat, flushing of the face, headache, vomiting, quick pulse, cutaneous eruption, excitability, and even delirium. *The antidote is morphine*. In persons who show such an idiosyncrasy, or in others in whom we wish to push the remedy, it is well to instruct the patient to press the finger against the lacrymal sac for several minutes after each instillation. When the susceptibility is very great, one of the *other mydriatics* (mentioned below) may be resorted to, or we may use a ten-per-cent. solution of *aqueous extract of belladonna* in water; *ophthalmic discs*, which contain very small doses, may prove useful in these cases.

Atropine Irritation.—In some persons atropine may cause considerable *local irritation*, showing itself in congestion, œdema of the lids, eczematous condition about the lids, and conjunctival (follicular) catarrh.

In using atropine or other solutions (miotics and anæsthetics), for the local effect upon the cornea or deeper portions of the eye, the drop is allowed to fall upon the cornea or into the lower conjunctival sac, the upper lid being raised, and the patient directed to throw the head back and to look down (Fig. 353). Such solutions are prescribed in small quantities (3 ij.) and labelled "*Poison.*"

Duboisine Sulphate (gr. $\frac{1}{2}$ to 3 ij.), Daturine Sulphate (gr. $\frac{1}{4}$ to 3 ij.), Hyoscyamine Hydrobromate (gr. $\frac{1}{2}$ to 3 ij.), and Scopolamine Hydrobromate (gr. $\frac{1}{8}$ to 3 ij.) are occasionally used as *substitutes for atropine*. They have similar attributes, are contraindicated in increased tension, and may also produce systemic poisoning.

Homatropine Hydrobromate resembles atropine in its actions, but is *milder*. It is very largely used to paralyze accommodation during the examination for *errors of refraction*. Though this effect is not so perfect as with atropine, it is *sufficient for all practical purposes*, and *lasts only 24 or 36 hours*, thus exposing the patient to very much less inconvenience. For refraction cases, it is usually used in two-per-cent. solution, one drop being instilled every five minutes, for four doses; half an hour after the final dose, the eye is ready for examination. It is frequently combined with cocaine for this purpose:

R Homatropin. hydro-	R Cocain. hydrochlor. . gr. i.
brom gr. ij.	Homatropin. hydro-
Aquæ destill. 3 ij. .	brom. gr. ij.
M.	Aquæ destill. 3 ij.
	M.

Euphthalmin is very useful for the purpose of dilating the pupil for *ophthalmoscopic examination*. The hydrochlorate is used in five- or ten-per-cent. solution; one or two drops cause mydriasis in thirty minutes, and the effects pass off in two or three hours. It has but a feeble action upon accommodation, and rarely causes increase in tension.

Cocaine Hydrochlorate is frequently used to produce *moderate dilatation* of the pupil for *ophthalmoscopic examination*. One or two drops of a four-per-cent. solution cause sufficient

dilatation in twenty minutes, produce *insignificant interference with accommodation*, and the effects disappear within an hour. Cocaine acts by constricting the blood-vessels of the iris. It *diminishes intraocular tension* (in rare cases the opposite effect has been observed). It is sometimes combined with other mydriatics, and then increases the action of the associated remedy.

MIOTICS.

Miotics *diminish the size of the pupil*. They produce tonic contraction of the *sphincter* and of the *ciliary muscle*, and *diminish intraocular tension*. These agents are employed chiefly in *glaucoma*; sometimes in ulcers of the cornea, especially when peripheral. *Eserine* ($\frac{1}{8}$ to $\frac{1}{2}$ per cent.) and *pilocarpine* ($\frac{1}{2}$ to 2 per cent.) are prescribed for these purposes. *Eserine* is *stronger*, and sometimes has a tendency to produce conjunctival irritation and iritis, and occasionally constitutional symptoms. *Pilocarpine* is *milder* and free from these drawbacks. It is sometimes given hypodermically to cause *diaphoresis* in certain diseases of the eye.

R Eserin. salicylat. gr. $\frac{1}{8}$ - $\frac{1}{4}$.

LOCAL ANÆSTHETICS.

Cocaine Hydrochlorate is the most commonly employed remedy for producing local anæsthesia of the conjunctiva, cornea, and to a certain extent the iris, during *operations* upon the eye. It may be used *subcutaneously* for operations upon the lid (occasionally subconjunctivally), due regard being exercised for its *poisonous qualities*. The *strength* of solution is usually two to four per cent. It is also of service as a *temporary anodyne* in corneal and iritic affections, and very useful as a *mydriatic* for ophthalmoscopic examinations. Its property of *lowering the intraocular tension* is sometimes a valuable feature. It is sometimes combined with atropine and homatropine, and occasionally with other remedies. Cocaine has a tendency to cause *desiccation of the cornea* and some-

times *superficial ulceration* ; hence after the instillation of this remedy, the patient should be directed to keep the lids closed ; for the same reason it is generally unwise to prescribe solutions of cocaine for home use.

One drop of a four-per-cent. solution, and a second drop after a few minutes, is sufficient to anæsthetize the cornea for the removal of foreign bodies ; for more penetrating effects, the instillations are repeated three or four times, at intervals of two or three minutes. Solutions of cocaine *do not keep well*, and should be *freshly prepared* previous to use in operations.

Holocain Hydrochlorate is an excellent local anæsthetic, manufactured synthetically, which is very *popular* and has *supplanted cocaine among many oculists*. It is usually employed in one-per-cent. solution. The *advantages* of this new remedy as compared with cocaine are: it acts more *quickly*, is more *penetrating*, does *not dilate the pupil*, is *not poisonous when applied locally*, and its *solution does not spoil*. It *cannot be used hypodermically*, since it causes toxic symptoms when employed in this way.

Eucaïn "B" is a local anæsthetic which was introduced as a substitute for cocaine. Its chief advantages are that it does not dilate the pupil and is *less poisonous* ; hence it is safer to use by the *hypodermic method*. But it causes some conjunctival irritation, and is not so uniform in its action as holocain or cocaine. It is employed hypodermically, but not often for instillation. It is used in five-per-cent. solution.

OTHER THERAPEUTIC MEASURES.

Adrenalin or Suprarenalin is the active principle of the *suprarenal gland*. It is available in 1:1,000 watery solution of the chloride, a colorless liquid, which can be diluted with salt solution of physiological strength. This remedy is a valuable *astringent and hæmostatic*. After instillation of solutions varying from 1:10,000 to 1:1,000, marked *blanching* of the conjunctiva occurs as a result of *contraction of the blood-vessels*, beginning in less than a minute and lasting half an hour or longer. When the ocular structures are very much congested,

cocaine or holocain produces unsatisfactory anæsthesia; if the instillation of these agents is followed by that of adrenalin or suprarenalin solution, the anæsthetic effect is very much more pronounced. This remedy is used in some cases of conjunctivitis with marked congestion, in affections of the lacrymal passages to facilitate the expression of retained contents and the introduction of probes, in operations upon the lacrymal sac, glaucoma, and in congested conditions of the eye in general, to blanch the tissues, thus permitting a more or less bloodless operation and making the action of local anæsthetics more satisfactory.

Dionine, a derivative of morphine, is an analgesic. It is recommended for the relief of pain in *iritis*, for the absorption of pupillary exudates and interstitial corneal deposits, as an aid to atropine in producing extreme dilatation of the pupil, and occasionally for the reduction of tension in glaucoma. This remedy is not a local anæsthetic, but it relieves deep-seated pain; it acts as a vasodilator and lymphagogue, stimulating the vascular and lymphatic circulation of the eye, producing marked dilatation of these vessels. The conjunctiva frequently becomes enormously swollen and the eyelids are sometimes included in this process, the eye occasionally assuming an alarming aspect; but there is no danger of serious consequences. It is employed in five- or ten-per-cent. aqueous solution, one or two drops being instilled into the lower conjunctival sac; occasionally it is used in powder or ointment form. Tolerance for the drug is established very rapidly, and after a week the characteristic reactions can no longer be produced.

Heat.—*Hot compresses* are prescribed in affections of the *cornea*, *iris*, and *ciliary body*. They are applied by means of flannel or absorbent cotton wrung out of water which is as hot as can be borne (115°); they are placed upon the *closed lids*, and *renewed every minute or two*.

Cold.—*Cold compresses* are used in *inflammatory affections of the conjunctiva*. The best method of applying them is as follows: Strips of lint, lintine, or similar material are folded so as to make *pads* of four thicknesses, about $1\frac{1}{2}$ inches square;

a number of these are moistened and laid upon a *block of ice*; from the ice they are transferred to the *closed eyelids*, and *changed* as soon as they become warm. In the absence of ice, the compresses may be wrung out of cold water. Ice should never be applied directly to the lids.

Electricity is not used frequently in ocular therapeutics, except in the form of the *electro-cautery* for ulcer of the cornea and conical cornea (p. 119). *Electrolysis* may be employed for the removal of distorted lashes (p. 41). *The galvanic and faradic currents* are occasionally resorted to in paralyses of ocular muscles, optic-nerve atrophy, and corneal opacities.

Local Blood-letting is of great benefit in affections of the *deeper structures* of the eye, especially in *iritis*. *Leeches* are very frequently prescribed; from two to four are applied to the temple, midway between the outer canthus and the tragus. The *artificial leech* (Fig. 159) is sometimes used in this situation, and an ounce of blood abstracted.

Massage is sometimes prescribed in *interstitial keratitis*, *glaucoma*, and in *corneal opacities*. A small quantity of some form of ointment is placed in the conjunctival sac; then the finger is applied to the closed upper lid, and the cornea massaged gently for a few minutes at a time.

Subconjunctival Injections are employed in episcleritis, scleritis, iridocyclitis, choroïditis, corneal ulcer, and in detachment of the retina.

After local anæsthesia by means of holocain or cocaine, a fold of conjunctiva is seized with forceps about 8 mm. from the limbus, the needle of a hypodermic syringe introduced into this lifted tissue, and from 5 to 15 minims of

FIG. 354.—Eye-Patch.

fluid injected; or the needle may be introduced superficially under the conjunctiva without the aid of a forceps when the patient looks downward and the upper lid is raised. Various germicides (mercury bichloride 1:5,000–1:1,000, mercury cyanide 1:5,000–1:1,000, cinnamic acid 1:100) have been recommended, but a solution of *sodium chloride* of physiological strength is equally effective and much less painful.

Protective Measures of various sorts are applied to the eye to *insure rest*, to *keep out light*, air, wind, and dust, and to *give support*. The patient is often kept in a *dark or shaded room* during the course of diseases of the retina and other deep structures. Various kinds of *smoked glasses*, of different tints, are prescribed: plane, curved (*coquilles*), and goggles. Mica glasses may be worn by stone-cutters. *Black Patches* (Fig. 354) and shades are made use of when imperfect protection is sufficient. The application of *eye bandages* is described on p. 375 (Figs. 359 and 360).

GENERAL CONSIDERATIONS OF OPERATIONS.

The strict rules of *asepsis and antisepsis* which govern modern general surgery are also indicated in ophthalmic operations, except that *strong solutions of germicides are not tolerated* by the eye. In other respects, the preparations connected with an operation are similar to those employed by the general surgeon.

Preparation of the Patient.—When operated upon in a hospital, the patient should become accustomed to his surroundings for twenty-four hours previous to operation. He should receive a *bath* and then take a mild *cathartic* the night before, followed by an *enema* on the morning of the operation. He should be in *good physical condition*; old age, albuminuria, and diabetes are no contraindications, but such patients often require special care.

It is imperative to examine the conjunctiva and the lacrymal sac before deciding to operate, especially if the operation be an important one upon the eyeball, such as iridectomy or cataract extraction. The presence of *purulent or muco-purulent secretion* from the conjunctiva or lacrymal sac renders an operation

upon the eyeball extremely hazardous, on account of the *danger of infection*. In such cases, the conjunctival or lacrymal affection must first be cured by appropriate treatment. In cases of doubt, it is well to bandage the eye for twenty-four hours, and then to examine the dressing.

Preparation of the Hands of the Operator.—The hands should be *scrubbed* thoroughly with soap and warm water, and then immersed for a minute in 1:1,000 corrosive sublimate solution. Rubber gloves are not worn during eye operations.

Preparation of Instruments.—*Blunt instruments* should be cleaned and polished, *boiled* in one-per-cent. solution of soda, rinsed with sterile water, and then kept in a *sterile solution* of salt (0.6 per cent.), or boric acid (4 per cent.), or dried and wrapped in *sterilized gauze*. *Sharp instruments* should be *cleaned* carefully, dipped into *boiling water* for one minute,

FIG. 355.—Drum Used to Test the Cutting Edges of Eye Instruments.

transferred to *alcohol*, and finally to *sterile solution* of salt (0.6 per cent.), or boric acid (4 per cent.), or else dried and covered with *sterilized gauze*; throughout this preparation great care must be taken not to injure the point or the cutting edge. Previous to sterilization, the cutting qualities are tested upon thin kid stretched in the testing-drum (Fig. 355), and before use the point and edges are examined with a magnifying lens.

Position of the Patient.—The patient may be operated upon either in bed, or on a table, or seated upon a special operating-chair (Figs. 356 and 357). The *light*, whether *daylight* or *artificial* illumination, must be good, and the field of operation must be well illuminated; for the latter purpose a *strong read-*

ing-glass is often used to throw the light upon the eye during operations upon the lens or iris.

Preparation of the Region of Operation.—The eyelids, including the lashes, brow, and the surrounding skin, should be

FIG. 356.—The Author's Examining and Operating Chair.

FIG. 357.—The Same Converted into an Operating Table.

rubbed thoroughly with *soap* and warm water, and then washed with *corrosive sublimate* solution (1:5,000). The *everted lids* are *cleansed* gently with solution of mercuric chloride, 1:5,000, or boric acid, 4 per cent., applied by means of absorbent cotton. The eyeball and lids are flushed with a large quantity of these solutions.

Anæsthesia.—In the great majority of adult cases, local anæsthesia is sufficient. Two drops of a four-per-cent. solution of hydrochlorate of *cocaine*, or of a one-per-cent. solution of *holocain* hydrochlorate, are instilled every few minutes for three or four doses, the lids being kept closed in the intervals. Cocaine solutions must be freshly prepared, since they do not keep well; in fact, it is safer to make and sterilize all solutions on the day of the operation.

In children and in nervous adults, also in enucleations, in glaucoma with very high tension, in blepharoplasty operations, and occasionally in other procedures, a *general anæsthetic* is necessary.

In operations upon the lid a one- or two-per-cent. solution of cocaine or of eucain B may be used *hypodermically*. A safer plan is to use the local infiltration method advocated by Schleich; but the œdematous and altered appearance of the lids following this procedure is often objectionable. General anæsthesia is usually resorted to in lid operations.

Cleansing Solutions.—In the course of operations upon the eyeball, it is necessary to *cleanse* the seat of operation, and to *irrigate the cornea* frequently to prevent desiccation. The solutions used for this purpose are *boric acid* 4 per cent., *salt* 0.6 per cent., and *mercuric chloride* 1:10,000. These cleansing solutions are applied either by means of an *undine* (Figs. 350, 352), a pipette or *eye-dropper* (Fig. 353), or small wads of absorbent cotton known as “*cotton sponges*.”

Dressings vary with the nature of the operation. *Steritized gauze and absorbent cotton*, used *dry* or *soaked* in antiseptic solutions (mercuric chloride, 1:5,000, or boric acid, 4 per cent.) are generally applied next to the closed eyelids, covered by an additional layer of dry cotton, and retained by a *bandage* covering one or both eyes, sometimes by strips of isinglass or rubber *plaster* (Fig. 358).

FIG. 358.—Gauze and Absorbent Cotton Dressing Retained by Plaster Strips.

Eye Bandages are $1\frac{1}{2}$ inches wide, 5 or 7 yards long, and made of *gauze*, *muslin*, or *flannel*. If used for *protection* only, they are applied *lightly*; if for *pressure*, they are put on *tightly*; in the latter case, care must be taken that the depression existing between supraorbital margin and nose, in which the eye is placed, is properly filled out.

The *Monocular Bandage* (Fig. 359) is applied as follows:

376 GENERAL CONSIDERATIONS OF EYE OPERATIONS.

Begin over the temple of the same side as the affected eye (the right, for example); make one turn around the forehead, then pass across the occiput, below the right ear, and obliquely across the right eye; then another turn about the forehead, below the right ear, across the right eye, alternating in this way three or four times.

The Binocular Bandage (Fig. 360).—Begin over the temple of one side—the right, for example; make a full turn around the forehead and continue to the left temple, then obliquely

FIG. 359.—Monocular Bandage.

FIG. 360.—Binocular Bandage.

across the occiput, below the right ear, across the right eye; around the upper occipital region, above the right ear, downward over the left eye, below left ear, across the occiput; below the right ear, across the right eye, and alternate in this manner for three or four turns.
